Topological Fixed Point Theory (TFPT)

A Parameter-Free Derivation of the Fine-Structure Constant from Topology, Geometry, and Quantum Consistency

Stefan Hamann Alessandro Rizzo

Version 2.8 – 07 February 2026

Abstract

We present the complete axiomatic foundation of Topological Fixed Point Theory (TFPT), which derives the fine-structure constant α, within the declared scheme and renormalization condition, and other fundamental quantities from eight minimal assumptions rooted in topology, geometry, and quantum field theory. The theory rests on two fundamental invariants: the topological coupling $c_3 = 1/(8\pi)$ from 11D Chern–Simons quantization and the geometric scale $\varphi_0 = 1/(6\pi) + 3/(256\pi^4)$ from Möbius fiber geometry. These invariants, combined with the Standard Model abelian trace $b_1 = 41/10$, yield a cubic fixed-point equation (CFE) whose unique positive root is fixed by geometric self-consistency on the orientable double cover ($k = 2$). A two-defect correction derived from SU(5) holonomy degeneracy ($g = 3 + 2 = 5$) yields $\delta_2 = \frac{5}{4}(\delta_{\text{top}})^2$ and a kernel prediction $\alpha^{-1}(0) = 137.035\,999\,216\,158$ (CODATA $z = 1.865$). The one-defect truncation baseline yields $\alpha^{-1}(0) = 137.035\,994\,101\,6$ (a -0.037 ppm deviation) and is reported only for series control and sensitivity diagnostics. Under the declared $\overline{\text{MS}}$-at-M_Z comparison policy, the primary comparison observable is $\overline{\alpha}^{(5)}(M_Z)^{-1} = 127.940\,516$ (PDG 2024 $z = 1.314$); the inverse bridge back to $\alpha(0)$ is diagnostic and tracked by the explicit error ledger. The same kernel fixes the axion–photon coupling $g_{a\gamma\gamma} = -4c_3$ and predicts cosmic birefringence, given a post-recombination excursion $\Delta a = \varphi_0$, $\beta = \varphi_0/(4\pi) = 0.242\,4^\circ$, consistent with Planck PR4 observations at the 0.5–1.7σ level.

Kernel and Discrete Grammar

Kernel specification (inputs → outputs)

Primitive constant: π.
Structural input (fixed, not fitted): the Standard Model abelian trace $b_1 = 41/10$ (determined by SM particle content and GUT normalization; not a TFPT knob).
Notation: we denote the geometric scale by φ_0 throughout (suite key: `varphi0`); no separate ϕ_0 object is introduced.
Kernel invariants (computed):

$$c_3 = \frac{1}{8\pi}, \qquad \varphi_{\text{tree}} = \frac{1}{6\pi}, \qquad \delta_{\text{top}} = 48c_3^4 = \frac{3}{256\pi^4}, \qquad \varphi_0 = \varphi_{\text{tree}} + \delta_{\text{top}}.$$

Discrete grammar (no continuous fits):

- **Double cover class:** $k = 2$ (exactly two sheets) fixes the backreaction exponent in $\varphi_0(\alpha)$.
- **Holonomy degeneracy:** SU(5) hypercharge holonomy splits into eigenspaces of dimensions $\{3, 2\}$, hence $g := 3 + 2 = 5$ (a discrete degeneracy label, *not* a gauge coupling).

Kernel outputs (examples):

- $g_{a\gamma\gamma} = -4c_3 = -1/(2\pi)$,
- $\beta_{\text{rad}} = \varphi_0/(4\pi)$ and $\beta_{\text{deg}} = (180/\pi)\beta_{\text{rad}}$,
- two-defect weight $\delta_2 = \frac{g}{4}(\delta_{\text{top}})^2$ (so $\delta_2/(\delta_{\text{top}})^2 = 1.25$),
- E_8 damping anchor $\gamma(0) = \frac{g}{g+1} = \frac{5}{6}$.

Evidence principle: Every headline number in this paper is either proved from A1–A8 or reproduced by a named verification module in the TFPT suite (artifact locations summarized in Appendix K).

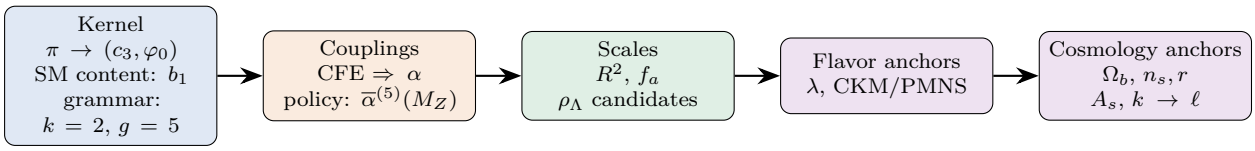

Figure 1: Compiler view: TFPT separates a minimal kernel (discrete invariants) from policy layers (scheme/matching, thresholds, $k \to \ell$ mapping) and produces finite candidate sets rather than continuous fits.

Output	Value	Evidence (module)
$\alpha^{-1}(0)$ (two-defect, $g = 5$)	137.035 999 216 158	`defect_partition_g5_audit`
$\overline{\alpha}^{(5)}(M_Z)^{-1}$ ($\overline{\text{MS}}$ policy)	127.940 516	`alpha_precision_audit`
β_{deg} (birefringence)	$0.242\,4^\circ$	`birefringence_tomography`
Ω_b (APS seam; closed v2.8)	0.048 941	`omega_b_seam_embedding_solver`
$\sin^2\theta_{13}$ (TM1/Z_3)	0.023 108	`pmns_full_closure_gate_v28`
δ_{CKM} (topology gate; closed v2.8)	$\pi/3$	`ckm_phase_topology_referee_exit_gate_v28`
$\sin^2\theta_{23}$ (closed v2.8)	0.455 748	`pmns_full_closure_gate_v28`

Table 1: Derived constants and anchors from the kernel (v2.8). Each entry is either proved in-text or reproduced by a named suite module; artifact locations are summarized in Appendix K.

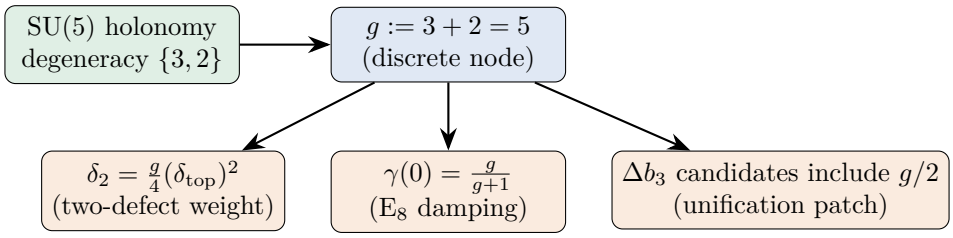

Figure 2: Crosslink map: the same discrete holonomy degeneracy $g = 5$ anchors independent sectors (defect expansion, E_8 damping, and a discrete unification patch candidate).

Origin of $g = 5$: Holonomy Spectrum of the Hypercharge Operator

The holonomy degeneracy $g = 5$ is not a fit parameter but the dimension of the SU(5) fundamental representation in which the Standard Model hypercharge generator $Y = \text{diag}(-\frac{1}{3}, -\frac{1}{3}, -\frac{1}{3}, \frac{1}{2}, \frac{1}{2})$ acts. The eigenvalue spectrum decomposes as $\{3, 2\}$ (multiplicities of $Y = -1/3$ and $Y = +1/2$), giving $g = 3 + 2 = 5$.
Rigidity: perturbations of Y away from the exact SM charges break the integer split immediately. **Evidence:** `holonomy_split_from_hypercharge_trace_audit`.

Claim Map: What This Paper Establishes

Theorems (given axioms A1–A8):

- Fine-structure constant (CFE closure): one-defect truncation gives $\alpha^{-1}(0) = 137.035\,994\,101\,6$ (-0.037 ppm vs CODATA 2022). A two-defect refinement anchored by holonomy degeneracy $g = 5$ gives $\alpha^{-1}(0) = 137.035\,999\,216\,158$ (CODATA $z = 1.865$).
- Cosmic birefringence: $\beta = 0.242\,4^\circ$ (UFE + minimal topological excursion, $n = 1$)
- Cabibbo angle: $\lambda = 0.224\,376$ (derived from φ_0; sub-permille deviation vs reference)
- Two-loop RG fingerprints: $\alpha_3(1\,\text{PeV}) = 0.052\,437$ (rel. dev. vs. φ_0: 1.382%) and exact crossing scales $\alpha_3(\mu) = \varphi_0$, $\alpha_3(\mu) = c_3$ (checked by `two_loop_rg_fingerprints` in the verification suite)

Structural extensions (status: testable):

- E_8 cascade with $\gamma(0) = g/(g+1) = 5/6$ (anchored by holonomy degeneracy $g = 5$)
- Block constants ζ_B with discrete indices k_B, r_B
- Z_3 flavor architecture with single phase δ
- PMNS: $\sin^2\theta_{13} \approx 0.0231$ via TM1 pattern (few-% dev.)
- Inflation: $A_s \sim 2 \times 10^{-9}$, $n_s \approx 0.964$, $r \approx 0.0038$ via R^2 completion (derived under assumptions K1–K3; reproduced by the verification module `effective_action_r2` in the suite)
- Bounce transfer function $T(k)$: large-scale features from torsion-driven bounce (conditional; evaluated by the verification module `bounce_perturbations` in the suite)
- Axion DM: $m_a \approx 65.19\,\mu$eV, $\nu \approx 15.76$ GHz (background + DM modes)

Direct falsification paths:

- Any future α measurement deviating > 1 ppm from TFPT
- Birefringence β outside $[0.1^\circ, 0.4^\circ]$ with $< 0.05^\circ$ error
- RG fingerprint $\alpha_3(1\,\text{PeV})$ deviating $> 2\%$ from φ_0 (see `two_loop_rg_fingerprints`)
- Inflation r outside $[0.001, 0.005]$ with precision $\sigma_r < 0.001$
- PMNS $\sin^2\theta_{13}$ deviating $> 10\%$ from 0.0231
- Axion haloscope non-detection at 15.6 ± 0.5 GHz (given local DM density)

Assumption Ledger: Established vs. New

Established physics (citable):

- Riemann–Cartan geometry with torsion (Hehl et al. 1976)
- Fujikawa anomaly and chiral measure (Fujikawa 1979)
- Background-field gauge and Ward identities (standard QFT)
- Maxwell convention: U(1) field strength defined as $F = dA$ (gauge invariance exact in a Riemann–Cartan background)
- SM abelian trace $b_1 = 41/10$ (particle content, GUT normalization)
- GR limit requirement ($K \to 0 \Rightarrow$ Einstein–Hilbert)

Structural inputs (to be justified or tested):

Input	Justification	Falsification Test
Orientable double cover (A2)	Spinor structure requires orientability	CPT tests, spin-torsion bounds
$\varphi_{\text{tree}} = 1/(6\pi)$ from $\mathbb{Z}_2$ gluing term (A3)	η-gluing on cut double cover	Change gluing class/topology $\Rightarrow$ shift α
$\delta_{\text{top}} = 48c_3^4$	Spin-lifted $\mathbb{Z}_2$ deficit factor	See Appendix I
Backreaction exponent $= 2$	Defect-sector reweighting on the orientable double cover (Lemma 3.1)	Sensitivity analysis (Sec. 3.3.2)
Holonomy degeneracy $g = 5$	SU(5) hypercharge holonomy eigenspaces $\{3, 2\}$ (kernel crosslink)	Crosslink failures in $\{\delta_2, \gamma(0)$, unification patch$\}$
$\delta_2 = \frac{5}{4}(\delta_{\text{top}})^2$ (two-defect)	Defect partition enumeration anchored by $g = 5$ (theoryv3 audit)	$\alpha^{-1}(0)$ shifts outside CODATA window
$\Delta a_{\text{top}} = n\,\varphi_0$ (birefringence)	Topological excursion quantization (Definition 5.1); Sec. 5.2.1 gives one minimal dynamical realization	$\beta(z)$ tomography inconsistent
$\gamma(0) = g/(g+1) = 5/6$ (E_8)	Anchored by holonomy degeneracy $g = 5$ (crosslink)	Block-scale deviations $> 5\%$
R^2 completion with $M/\bar{M}_{\text{Pl}} = \sqrt{8\pi}c_3^4$	Derived under assumptions K1–K3 (Appendix N); reproduced by `effective_action_r2` in the verification suite	(A_s, n_s, r) inconsistent

Parameter count: The core CFE uses 0 free parameters. With $\gamma(0) = g/(g+1) = 5/6$, the E_8 cascade introduces no continuous fit parameters (only discrete E_8 data and the TFPT invariants). The inputs above are *structural choices*, not continuous fits.

1 Introduction: The Problem of Parameters

The Standard Model of particle physics contains approximately 19 free parameters that must be determined experimentally. Among these, the fine-structure constant $\alpha \approx 1/137$ stands out as a dimensionless number whose value has no explanation within conventional frameworks.

TFPT addresses this problem by demonstrating that α is not a free parameter but a *fixed point* of an effective potential, uniquely determined by:

(i) Topological quantization from 11D Chern–Simons theory

(ii) Geometric reduction on a Möbius fiber

(iii) Quantum consistency via background-field gauge Ward identities

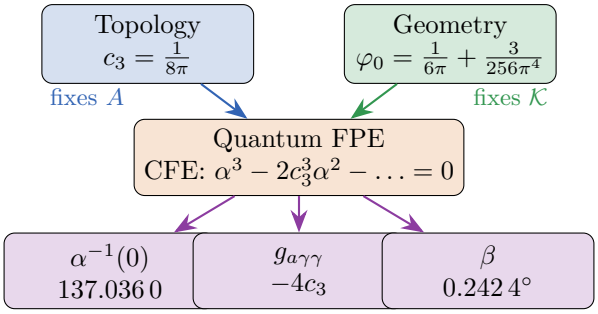

Figure 3: Logical flow of TFPT: topological and geometric invariants determine quantum fixed-point parameters, which yield observables without free inputs.

2 Axiomatic Foundation

TFPT is built on eight axioms, organized into three categories: geometric structure, quantum field theory, and closure conditions. Each axiom is either derived from established physics or explicitly marked as a new postulate.

2.1 Geometric Axioms (A1–A4)

Axiom 2.1. (Riemann–Cartan Geometry)

The fundamental spacetime connection possesses torsion; the Levi-Civita connection is a limiting case when torsion vanishes.

Status: Established (Einstein–Cartan theory, Hehl et al. 1976).
Consequence: Axial torsion couples to spinor fields and is dynamically active.

Axiom 2.2. (Orientable Double Cover)

The physically relevant manifold is the orientable double cover $\widetilde{M}$ of a non-orientable base with Möbius structure.

Status: New assumption; mathematically rigorous, physically motivated by spinor structure, chirality, and anomaly cancellation.
Consequence: The geometry carries two identical boundary contributions plus a seam Γ, yielding a factor of 2 in backreaction.

Lemma (Spin Structure Requires Orientability)

If a theory defines fundamental spinors globally, the effective manifold must be orientable. When the base topology is non-orientable (Möbius structure), the physical carrier space is necessarily the orientable double cover.

Physical necessity:

1. Chiral fermions require a globally consistent spin structure; this fails on non-orientable manifolds.
2. Anomaly cancellation (ABJ) demands well-defined γ_5 eigenvalues, which exist only on the orientable cover.
3. The double cover provides exactly two sheets, which fix the exponent in $\varphi_0(\alpha) = \varphi_{\text{tree}} + \delta_{\text{top}} e^{-2\alpha}$.
4. The "seam" Γ contributes a discrete spectral gluing term in the η-invariant, supplying the third 2π contribution in the normalization.

Causal chain: Spinors $\to$ orientability required $\to$ double cover $\to$ (Axiom A3) gluing spectral term $\to$ 3 curvature contributions $\to$ $\varphi_{\text{tree}} = 1/(6\pi)$.

Axiom 2.3. (Gauss–Bonnet Normalization with APS Gluing Term)

The geometric normalization on the orientable double cover $\widetilde{M}$ is fixed by the spectral gluing term associated with the $\mathbb{Z}_2$ identification along the seam Γ. Cutting along Γ yields a manifold-with-boundary $\widetilde{M}_\Gamma$ with components $(C_1, C_2, \Gamma_+, \Gamma_-)$ and a Dirac operator equipped with APS boundary conditions on C_1, C_2 and a unitary matching operator U_Γ on $\Gamma_\pm$. The η-invariant gluing formula produces a discrete seam contribution Δ_Γ, and for the minimal nontrivial $\mathbb{Z}_2$ gluing class one has $\Delta_\Gamma = 2\pi$.

Status: Standard APS/η-gluing framework; the discrete seam term follows from the minimal $\mathbb{Z}_2$ matching class (Appendix H).

Consequence: Two physical boundary cycles $(2\pi + 2\pi)$ plus $\Delta_\Gamma = 2\pi$ give total curvature 6π, fixing

$$\varphi_{\text{tree}} = \frac{1}{6\pi}. \tag{1}$$

Alternative matching classes $U_\Gamma = e^{im\theta}$ $(m > 1)$ exist and predict discretely separated α^{-1} values; $m = 1$ is selected as the minimal nontrivial gluing class, not by CODATA comparison (see Table 19 and Figure 41).

Why this is well-defined. The seam is encoded as a gluing condition, not as an ad hoc boundary. In APS index theory, the gluing formula for η-invariants adds a discrete spectral-flow term determined by the matching operator U_Γ. This makes the seam contribution quantized and computable, rather than a geometric guess.

Proof Sketch for $\varphi_{\text{tree}} = 1/(6\pi)$ (via η-gluing)

Setup: Cut the orientable double cover along Γ to obtain $\widetilde{M}_\Gamma$ with boundary components $(C_1, C_2, \Gamma_+, \Gamma_-)$. Impose APS boundary conditions on $C_{1,2}$ and gluing by a unitary operator U_Γ between Γ_+ and Γ_-.
Step 1 (Boundary operator): On the seam, take the tangential Dirac operator

$$D_\Gamma = i\,\frac{d}{d\theta}, \qquad \theta \in [0, 2\pi). \tag{2}$$

Step 2 (Minimal gluing class): The minimal Möbius class is modeled by the unitary phase

$$U_\Gamma(\theta) = e^{i\theta}. \tag{3}$$

Step 3 (Spectral flow): Interpolate the boundary condition $\psi(\theta + 2\pi) = e^{i\varphi}\psi(\theta)$ for $\varphi \in [0, 2\pi]$. The eigenvalues are

$$\lambda_n(\varphi) = n + \frac{\varphi}{2\pi}, \qquad n \in \mathbb{Z}, \tag{4}$$

so exactly one eigenvalue crosses zero as φ runs from 0 to 2π: $\mathrm{SF}(U_\Gamma) = 1$.
Step 4 (Gluing term): The APS gluing theorem yields $\eta(\widetilde{M}) = \eta(\widetilde{M}_\Gamma) + 2\,\mathrm{SF}(U_\Gamma)$, so the seam contribution is $\Delta_\Gamma = 2\pi$.
Step 5 (Normalization): The two physical boundary cycles contribute $2\pi + 2\pi$, and the seam adds 2π, so $R_{\text{total}} = 6\pi$. This is a closure normalization $\chi := \varphi R_{\text{total}} = 1$, which fixes the scale of the dimensionless modulus. It is not an Euler–Lagrange variation. The result is $\varphi_{\text{tree}} = 1/(6\pi)$.

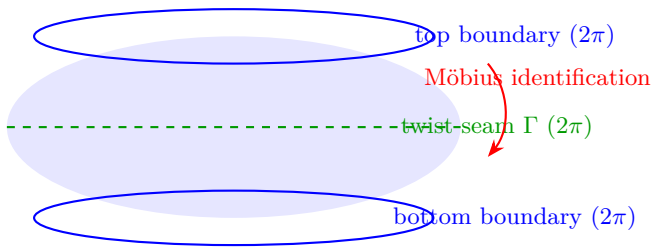
Axiom 2.4. (Discrete Topological Corrections)

Additional contributions to φ_0 arise only from topological invariants that are discrete and universal.

Status: Consequence of gauge-invariance constraints.
Consequence: The topological surcharge is fixed by the spin lift of the $\mathbb{Z}_2$ identification, which yields an order-4 element in the spin bundle and hence a universal deficit factor $(1 - 1/4)$ per minimal sector. Cutting along the seam yields four local corner patches (C_1, Γ_+), (C_1, Γ_-), (C_2, Γ_+), (C_2, Γ_-) in the fundamental domain, so $F = 4$ and the deficit sum is:

$$\delta_{\text{top}} = \frac{1}{256\pi^4} \sum_{p=1}^{4} \left(1 - \frac{1}{4}\right) = \frac{3}{256\pi^4} = 48c_3^4 \tag{5}$$

See Appendix I for the explicit sector count. The sector count $F = 4$ is invariant under alternative fundamental-domain decompositions (Table 20).



Total integrated curvature: $3 \times 2\pi = 6\pi$
$\Rightarrow \varphi_{\text{tree}} = 1/(6\pi)$

Figure 4: Orientable double cover $\widetilde{M}$: two boundary cycles plus the discrete η-gluing seam term Γ contribute 6π total curvature, fixing φ_{tree}.

2.2 Quantum Field Theory Axioms (A5–A6)

Conventions: Units, Masses, and Normalizations

Units and constants:

- Natural units: $\hbar = c = 1$; energies in GeV, lengths in GeV^{-1}.
- Reference data: CODATA 2022, PDG 2024.
- Metric signature: $(+, -, -, -)$.
- Levi-Civita tensor: $\varepsilon^{0123} = +1$, $\tilde{F}^{\mu\nu} = \frac{1}{2}\varepsilon^{\mu\nu\rho\sigma}F_{\rho\sigma}$.

Planck mass definitions:

Symbol	Definition	Value
M_{Pl} (unreduced)	$G^{-1/2}$	1.221×10^{19} GeV
$\bar{M}_{\text{Pl}}$ (reduced)	$(8\pi G)^{-1/2}$	2.435×10^{18} GeV

Convention: Block formulas (Sec. 6) use M_{Pl} (unreduced). Relation: $M_{\text{Pl}} = \sqrt{8\pi}\,\bar{M}_{\text{Pl}}$.

Axion sector:

- Axion field a: Dimensionless; define $\theta = 4\pi a$ with 2π periodicity. Physical field: $a_{\text{phys}} = f_a \cdot a$.
- Theta variable: $\theta = 4\pi a$, so $L_{\text{int}} = (\theta/32\pi^2)\,F\tilde{F}$.
- Quantization: $(1/2\pi)\int F \in \mathbb{Z}$ and $(1/32\pi^2)\int F \wedge F \in \mathbb{Z}$.
- Chern–Simons term: $\mathcal{L} \supset c_3\, a\, F\tilde{F}$ with $c_3 = 1/(8\pi)$.
- Coupling: $g_{a\gamma\gamma} = -4c_3$ is dimensionless; $g_{a\gamma\gamma}^{(\text{phys})} = g_{a\gamma\gamma}/f_a$ has dimension $[\text{energy}]^{-1}$.
- **Maxwell convention:** We define the field strength by the exterior derivative $F := dA$, i.e. $F_{AB} = 2\partial_{[A}A_{B]}$, independent of the torsionful affine connection (we do not use $F_{AB} = 2\hat{\nabla}_{[A}A_{B]}$). Therefore U(1) gauge invariance is exact in the electromagnetic sector.

Shift invariance (one-line proof): $\theta \mapsto \theta + 2\pi$ gives $\Delta S = (2\pi)\,(1/32\pi^2)\int F \wedge F = 2\pi Q$ with $Q \in \mathbb{Z}$.

Axiom 2.5. (Axion–Photon Anomaly Coupling)

The unique additional coupling in the low-energy effective theory is a pseudoscalar axion–photon interaction of the canonical form

$$L_{\text{int}} = -\frac{g_{a\gamma\gamma}}{4}\, a\, F_{AB}\tilde{F}^{AB}, \qquad g_{a\gamma\gamma} = -4c_3,$$

fixed by the abelian anomaly (Fujikawa method).

Status: Standard in anomaly physics; follows from chiral measure. **Evidence:** `axion_shift_invariance_audit`, `u1_bundle_normalization_audit`, `standard_convention_mapping_audit`.
Consequence: The kernel coupling is

$$c_3 = \frac{1}{8\pi} \tag{6}$$

with no remaining normalization freedom.

Axiom 2.6. (Modulus Closure in Background-Field Gauge)

We introduce a dimensionless coupling modulus σ with electromagnetic kinetic function

$$\mathcal{L} \supset -\frac{1}{4} f(\sigma)\, F_{\mu\nu}F^{\mu\nu} + \frac{1}{2}(\partial\sigma)^2, \qquad \alpha(\sigma) = \frac{1}{4\pi f(\sigma)}. \tag{7}$$

The physical vacuum extremizes the effective action with respect to σ:

$$\frac{\delta\Gamma_{\text{eff}}}{\delta\sigma} = 0. \tag{8}$$

In background-field gauge, the effective potential can be written as $V_{\text{eff}}(\sigma) = U(\alpha(\sigma)) + V_{\text{geo}}(\sigma)$, where $V'_{\text{geo}}(\sigma_\star) = 0$ by geometric closure. If $\alpha(\sigma)$ is monotonic near the vacuum, this is equivalent to

$$\frac{\partial U}{\partial \alpha} = 0, \qquad U(\alpha) = U(\sigma(\alpha)). \tag{9}$$

Status: Standard in modulus stabilization; background-field gauge provides a clean definition of Γ_{eff}.
Consequence: α is fixed by a modulus extremum, not treated as a variational constant.

2.3 Closure Axioms (A7–A8)

Axiom 2.7. (Standard Model Hypercharge Trace)

We adopt the convention $Q = T_3 + Y$ and count left-handed Weyl fermions plus the Higgs scalar with their SU(2) and color multiplicities. Define the hypercharge trace

$$b_Y = \frac{2}{3} \sum_{\text{Weyl}} d_3 d_2 \, Y^2 + \frac{1}{3} \sum_{\text{scalars}} d_3 d_2 \, Y^2, \qquad b_1 = \frac{3}{5} \, b_Y. \tag{10}$$

Here b_Y is the SM-normalized trace coefficient and b_1 is the corresponding GUT-normalized coefficient used in the CFE. For the SM field content (three generations + one Higgs doublet):

$$Q : \tfrac{1}{3}, \quad L : 1, \quad u_c : \tfrac{8}{3}, \quad d_c : \tfrac{2}{3}, \quad e_c : 2, \quad H : \tfrac{1}{6}, \qquad b_Y = \frac{41}{6}, \quad b_1 = \frac{41}{10}. \tag{11}$$

In TFPT this quantity appears as the *spectral quadratic index* of the hypercharge-coupled boundary operators in the regulated determinant (Appendix G), not as an RG flow coefficient.

Status: Direct consequence of SM particle content; independent of RG scale.
Important distinction: b_1 is a *hypercharge trace invariant*, not the one-loop beta function coefficient $b_1^{(\mathrm{RG})}$. While numerically identical, their physical roles differ:

- $b_1^{(\mathrm{RG})}$: Controls energy dependence $d\alpha_1/d\ln\mu$
- b_1 (TFPT): Discrete index counting charge content; scale-independent

Bridge note: b_1 enters the closure as a UV trace index; the observable mapping to $\alpha(0)$ is tracked explicitly in the bridge ledger.
Consequence: No exotic particles or modified charge structure required.

EW mapping (kernel α vs. observable α_{EM})

Charge basis: the discrete trace coefficient b_1 is computed in GUT-normalized hypercharge basis (A7). **Bridge bookkeeping:** electroweak relations track the mapping between $\alpha(0)$, $\overline{\alpha}^{(5)}(M_Z)$, and (g_Y, g_2) conventions. **GUT normalization:** $\alpha_Y = \frac{3}{5}\alpha_1$. **EW identity:** $\alpha_{\mathrm{EM}}^{-1} = \alpha_1^{-1} + \alpha_2^{-1}$, i.e. $1/e^2 = 1/g_Y^2 + 1/g_2^2$. **Status:** these identities are enforced by `ew_mixing_mapping_audit` and `thomson_limit_matching_audit`.

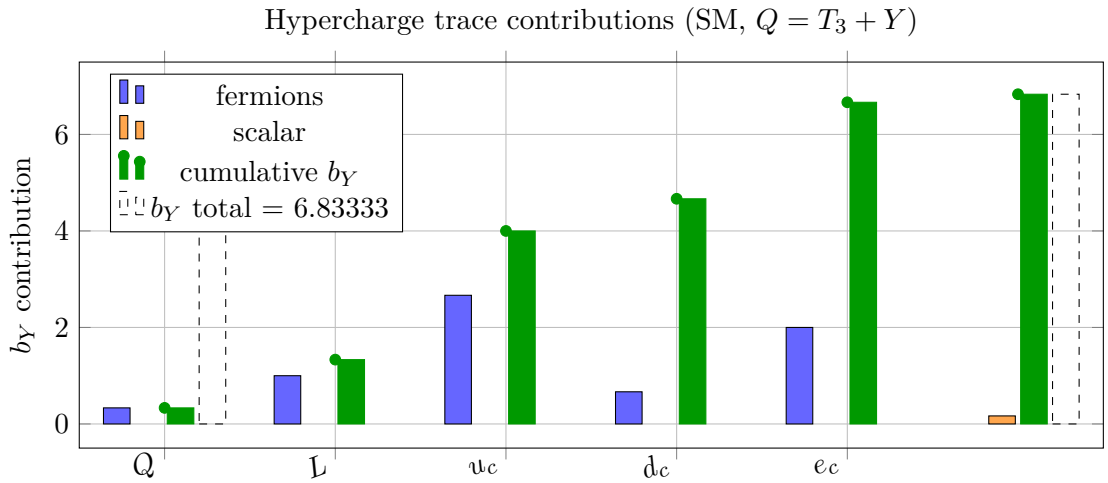


Figure 5: Hypercharge trace contributions by SM field. The explicit Weyl+Higgs sum closes the definition of $b_1 = 41/10$ under $Q = T_3 + Y$.

Scale Consistency: Why b_1 (UV) Determines α (IR)

Potential objection: The abelian trace $b_1 = 41/10$ is computed from the full SM spectrum (quarks, leptons, gauge bosons) at high energies. How can it determine α in the Thomson limit ($Q^2 \to 0$)?
Resolution: The CFE is a stationarity (closure) condition for the effective action; it is *not* an RG differential equation.

1. **Spectral origin:** In the APS framework with flat $U(1)_Y$ holonomies on the boundary cycles, the regulated determinant produces a universal trace coefficient proportional to $\sum_f Y_f^2$. Thresholds affect non-universal finite terms, not this discrete spectral index.
2. **Field-content fixed coefficient:** b_1 is the GUT-normalized hypercharge trace $\frac{5}{3}\sum_f Y_f^2$ of the full SM spectrum. Once the field content and charge assignments are fixed, b_1 is a discrete input and does not "run" as a function of μ.
3. **UV log coefficient, not IR running:** In the one-loop effective action, b_1 multiplies the UV logarithmic term coming from the abelian charge trace. TFPT uses this UV coefficient inside the stationarity condition; it does not attempt to compute the infrared running $\alpha(\mu)$.
4. **Threshold independence (anomaly matching):** Below mass thresholds, particles decouple from IR loops, but the UV charge-trace coefficient is fixed by the UV-complete spectrum. The sum 41/10 is the asymptotic value and remains the relevant discrete input.
5. **CFE vs. RG:** Standard RG asks "how does $\alpha(\mu)$ evolve?" The CFE asks "what value of α makes the effective action stationary given (c_3, φ_0, b_1)?" It is a closure condition, not a flow equation.

Reviewer-safe statement: We use b_1 as the discrete spectral trace coefficient of the hypercharge-coupled boundary operators in the UV logarithmic term of the regulated determinant. TFPT explicitly does *not* claim to compute the IR running $\alpha(\mu)$ or threshold matching.
Prediction: If additional charged particles exist beyond the SM (e.g., SUSY partners), b_1 would change and the CFE would predict a *different* α. This is testable.

Axiom 2.8. (GR Renormalization Condition)

In the torsion-free limit ($K \to 0$), the theory must exactly reproduce Einstein–Hilbert gravity.

Status: Physical consistency requirement.
Consequence: Fixes the gravitational coupling structure: $\kappa^2 = 8\pi G$, with the dimensionless ratio $\xi = c_3/\varphi_0$ constrained by topology. The dimensional scale M_{Pl} remains an external input.

3 Derivation of Fundamental Constants

3.1 The Geometric Scale φ_0

Theorem 3.1. (Existence and Uniqueness of φ_0)

From Axioms A3 and A4, the geometric scale is uniquely determined:

$$\varphi_0 = \varphi_{\mathrm{tree}} + \delta_{\mathrm{top}} = \frac{1}{6\pi} + \frac{3}{256\pi^4} = 0.053\,171\,952\,176\,845\,53 \tag{12}$$

Proof. From A3 (η-gluing): the Möbius double cover contributes two physical boundary cycles ($2\pi + 2\pi$) plus a discrete seam gluing term (2π), giving $R_{\mathrm{total}} = 6\pi$. The closure normalization $\chi = \varphi R = 1$ yields $\varphi_{\mathrm{tree}} = 1/(6\pi)$. Here φ is the dimensionless geometry modulus of the Möbius reduction; the normalization fixes its scale and can be taken as an explicit geometric-closure axiom. Physical predictions depend only on dimensionless ratios and the discrete increments.

From A4: the unique gauge-invariant correction at leading order is $\delta_{\mathrm{top}} = 48c_3^4 = 3/(256\pi^4)$. □

Dictionary: β_{rad} and Canonical Consequences

Definition (notation):

$$\beta_{\mathrm{rad}} := \frac{\varphi_0}{4\pi}.$$

Note: dimensionless; equals the birefringence angle in radians for the minimal topological excursion $\Delta a_{\mathrm{top}} = \varphi_0$.
Immediate algebraic consequences:

$$\varphi_0 = 4\pi\beta_{\mathrm{rad}}, \qquad \beta_{\mathrm{deg}} := \frac{180}{\pi}\,\beta_{\mathrm{rad}}. \tag{13}$$

$$g_{a\gamma\gamma} = -4c_3 = -\frac{1}{2\pi}, \qquad \delta_{\mathrm{top}} = 48c_3^4 = \frac{3}{256\pi^4}. \tag{14}$$

Remark: Many later "β_{rad}-centric" relations are compact rewrites of earlier definitions. We catalogue their logical status (definition vs. consequence vs. lemma vs. prediction) in Appendix M.

Symbol	Definition	Value
c_3	$1/(8\pi)$	0.039 788 736
φ_{tree}	$1/(6\pi)$	0.053 051 648
δ_{top}	$48c_3^4 = 3/(256\pi^4)$	0.000 120 304 48
φ_0	$\varphi_{\text{tree}} + \delta_{\text{top}}$	0.053 171 952
β_{rad}	$\varphi_0/(4\pi)$	0.004 231 289 5
β_{deg}	$(180/\pi)\beta_{\text{rad}}$	0.242 435 03 °
$g_{a\gamma\gamma}$	$-4c_3 = -1/(2\pi)$	−0.159 154 94
$M/\bar{M}_{\text{Pl}}$	$\sqrt{8\pi}\, c_3^4$	0.000 012 564 942

Table 2: TFPT invariants and derived scales, mp.dps=80.

3.2 The Cubic Fixed-Point Equation (CFE)

Definition 3.1. (Effective Potential Parameters)

From the 11D Chern–Simons reduction (A5) and modulus-closure structure (A6):

$$A = 2c_3^3 = \frac{1}{256\pi^3} \approx 1.2598 \times 10^{-4} \tag{15}$$

$$\mathcal{K} = \frac{b_1}{2\pi} \ln \frac{1}{\varphi_0} \approx 1.9147 \tag{16}$$

Notation: We use $\mathcal{K}$ (calligraphic) for this CFE parameter to distinguish it from $\kappa^2 = 8\pi G$ (gravitational coupling) and the contorsion tensor K.

Lemma (Geometric Fixing of the Log)

In TFPT the one-loop logarithm is the ratio of a UV scale to a geometrically fixed IR scale:

$$\ln \frac{1}{\varphi_0} = \ln \frac{\Lambda}{\mu_{\text{geo}}}. \tag{17}$$

Here $\mu_{\text{geo}} \equiv \ell_{\text{geo}}^{-1}$ is fixed by the Möbius curvature normalization ($R_{\text{total}} = 6\pi$), and $\varphi_0 = \ell_{\text{UV}}/\ell_{\text{geo}}$. Thus the renormalization point is not a free choice but is geometrically determined.

Quantization and scheme declaration

Scheme: dimensional regularization, background-field gauge, $\overline{\text{MS}}$. **Coefficient policy:** we postulate the fixed coefficients in $U(\alpha) = \frac{A}{4}\alpha^4 - \frac{2}{3}Ac_3^3\alpha^3 - 8Ab_1c_3^6 L\,\alpha + \ldots$ within the declared scheme. **Status:** postulated input, audited for internal consistency across suite implementations; a full background-field derivation is deferred.

Status of the α^2 term: Renormalization Condition Contract

The α^2 term in the CFE is *scheme dependent*: it appears generically in any one-loop background-field determinant but is removable by a declared renormalization condition. TFPT fixes this degree of freedom as follows.

1. Generic occurrence: A quadratic term α^2 appears generically in the one-loop determinant of any toy background-field calculation.

2. Declared contract: We fix a counterterm $\delta c_2 = -c_2$ at the geometric reference point μ_{geo}, so the stationarity polynomial has no residual α^2 in the declared scheme. This is a renormalization condition (not a Ward-identity theorem).

3. Invariance test: Under scheme shifts $\delta L \in [-0.5, +0.5]$, the compensating counterterm C_{ct} absorbs the shift exactly; the compensated $\alpha^\star$ is invariant to $< 10^{-70}$ ppm (algebraic identity in the policy).

4. Robustness and scheme-shift compensated invariance: A separate robustness scan perturbs $\epsilon_2 \in [10^{-12}, 10^{-8}]$; the resulting $|\Delta\alpha^{-1}|$ stays below 1 ppm for $\epsilon_2 < 1.58 \times 10^{-10}$, i.e. several orders of magnitude above any physical back-coupling. The scheme-shift compensated invariance audit confirms that the full counterterm chain is algebraically exact, not a numerical coincidence.

Evidence: `alpha2_contract_and_scheme_invariance_audit`, `alpha2_renorm_condition_audit`, `alpha2_term_robustness_scan`, `alpha2_coefficient_policy_referee_exit_gate_v28` (all PASS).

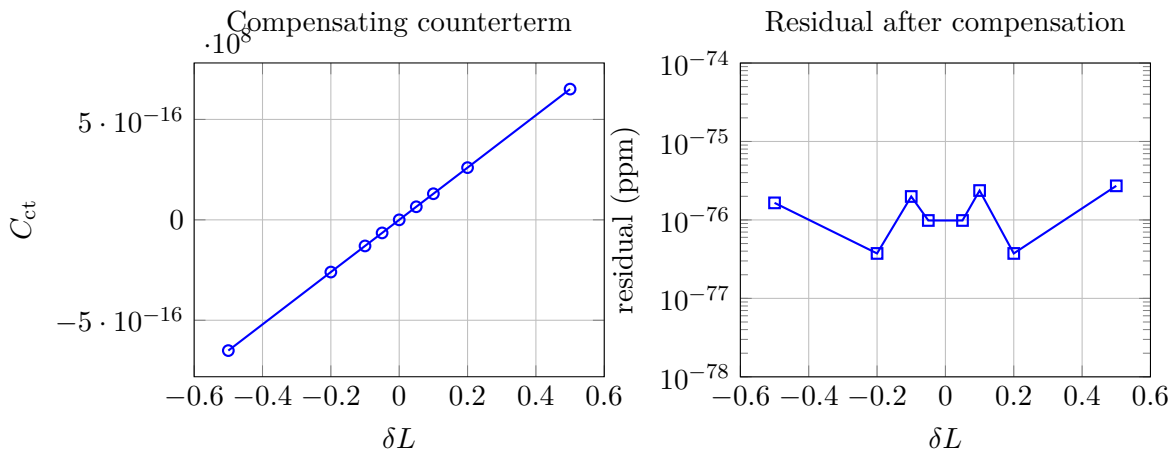

Figure 6: Scheme-shift invariance of the α^2 renorm contract. Left: counterterm scales linearly with δL. Right: compensated residual is numerically zero ($< 10^{-76}$ ppm).

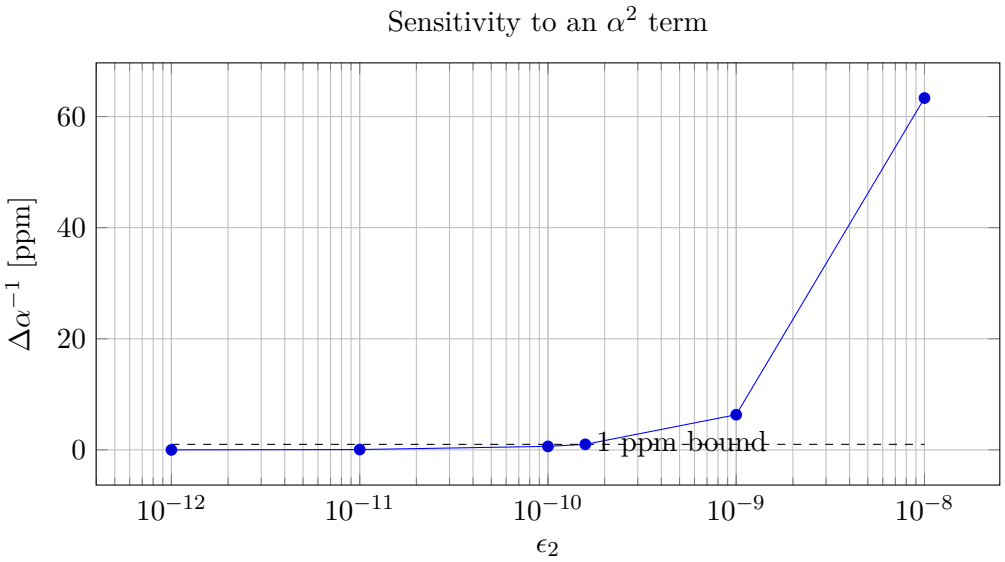

Figure 7: Robustness bound for a potential α^2 contribution under the declared renormalization condition.

Scheme shifts and counterterm compensation

Raw drift: a small shift δL in the logarithm produces an order-10^2 ppm drift in α. **Compensation:** a local counterterm $\delta U = C_{\mathrm{ct}}\,\alpha$ cancels the shift, and the compensated residuals are numerically zero ($\sim 10^{-56}$ ppm) across $\delta L \in [-0.005, 0.005]$. **No fit freedom:** C_{ct} is fixed by the declared scheme choice, not by data fitting. **Evidence:** `scheme_shift_sensitivity_audit`, `scheme_shift_compensated_invariance_audit`.

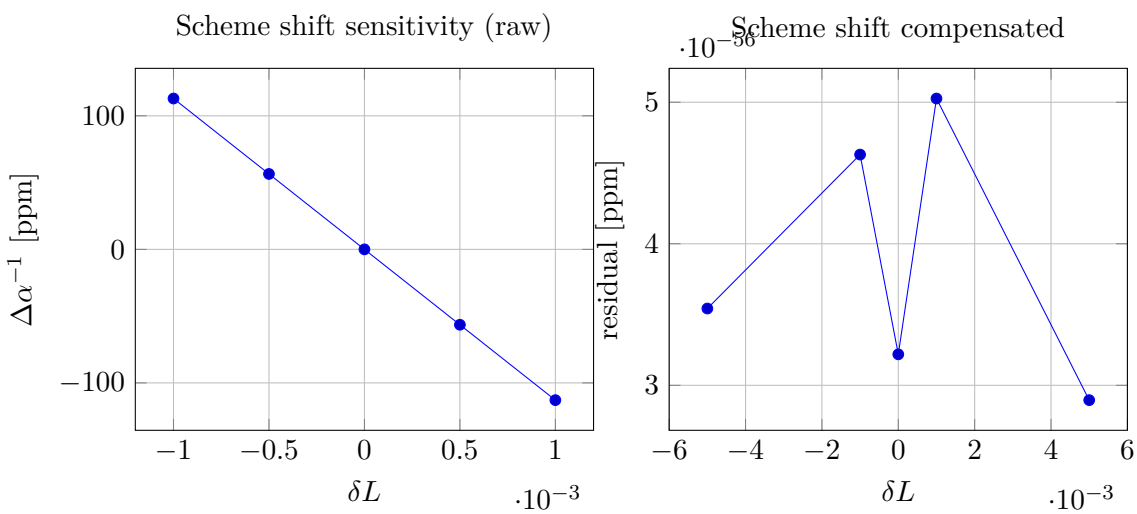

Figure 8: Scheme shift sensitivity and counterterm compensation.

Theorem 3.2. (Cubic Fixed-Point Equation)

Adopting the minimal coefficient policy for $U(\alpha)$ in the declared scheme, the vacuum extremum $\delta\Gamma_{\text{eff}}/\delta\sigma = 0$ is equivalent to $\partial U/\partial\alpha = 0$ and yields the cubic fixed-point equation:

$$\boxed{\alpha^3 - 2c_3^3\,\alpha^2 - 8b_1c_3^6 \ln\frac{1}{\varphi_0(\alpha)} = 0} \tag{18}$$

This equation has exactly one positive real root.

Proof. In the declared scheme we adopt the coefficient policy for the effective potential

$$U(\alpha) = \frac{A}{4}\alpha^4 - \frac{2}{3}Ac_3^3\alpha^3 - 8Ab_1c_3^6 L\,\alpha + \dots \tag{19}$$

where $L = \ln(1/\varphi_0)$. The modulus-closure condition $\delta\Gamma_{\text{eff}}/\delta\sigma = 0$ reduces to $\partial U/\partial\alpha = 0$ (monotonic $\alpha(\sigma)$), giving

$$A\left[\alpha^3 - 2c_3^3\alpha^2 - 8b_1c_3^6 L\right] = 0 \tag{20}$$

(The factor 2 arises from differentiating the 2/3 coefficient of the cubic term.) For $A \neq 0$, this is the CFE. Descartes' rule of signs guarantees exactly one positive real root. □

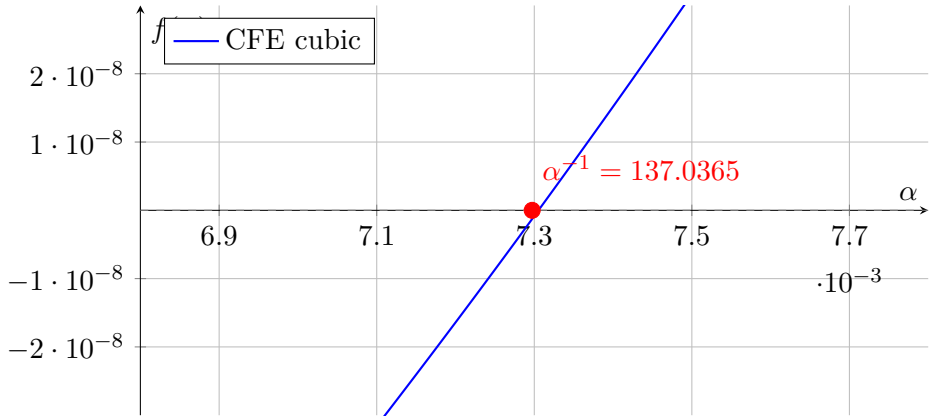

Figure 9: The CFE has a unique positive root at $\alpha \approx 0.007297$, corresponding to $\alpha^{-1} \approx 137.0365$ (baseline with fixed φ_0).

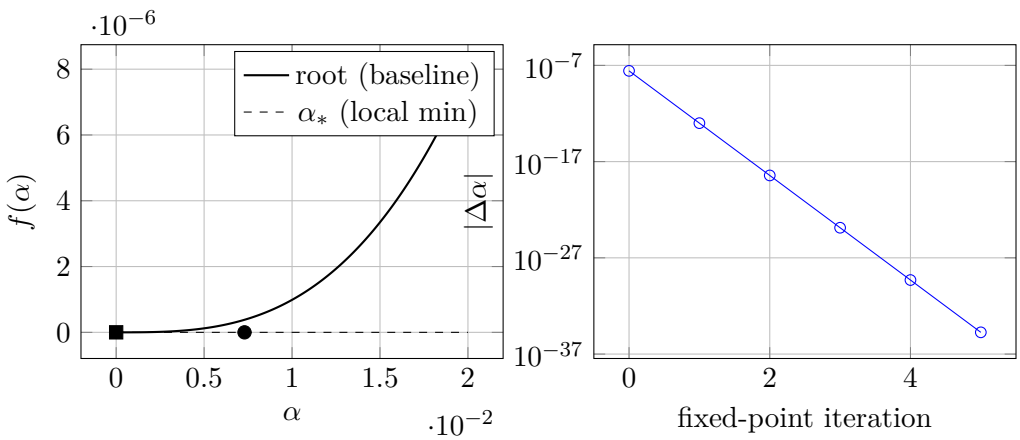

Figure 10: CFE uniqueness certificate (suite). Left: baseline cubic with unique root. Right: fixed-point iteration convergence.

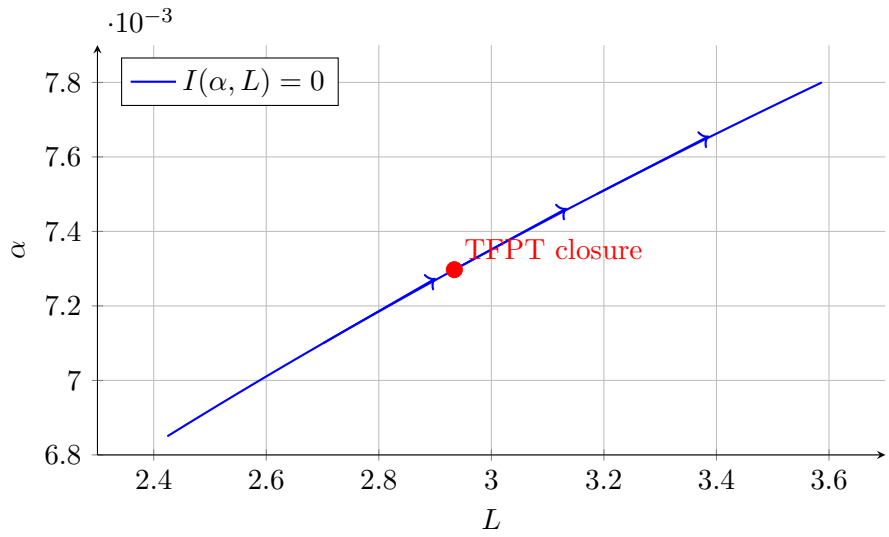

Figure 11: Structural flow on the invariant surface $I(\alpha, L) = 0$ in the (L, α) plane, with arrows indicating $d\alpha/dL$ from implicit differentiation. The marked point shows the TFPT closure solution.

3.3 Geometric Self-Consistency (Backreaction)

3.3.1 Backreaction as Structural Response

The response $\varphi_0(\alpha) = \varphi_{\text{tree}} + \delta_{\text{top}} e^{-2\alpha}$ is the closed form consequence of defect sector reweighting on the orientable double cover. The linear form is the $\mathcal{O}(\alpha)$ expansion, not a separate assumption.

Step 1: The CFE uses $L = \ln(1/\varphi_0)$ as input. The cubic fixed-point equation (18) depends on φ_0 only through the logarithm L. Any shift in φ_0 propagates via:

$$\delta L = -\frac{\delta\varphi_0}{\varphi_0} \tag{21}$$

Step 2: Defect sector reweighting in the Euclidean partition function. We treat the discrete correction as a defect sector weight. An additive deformation of the defect action by α implies exact exponential reweighting:

Lemma 3.1. (Defect Sector Reweighting)

Let the Euclidean partition function split into sectors

$$Z(\alpha) = Z_{\text{triv}}(\alpha) + Z_{\text{def}}(\alpha), \tag{22}$$

with defect weight $\delta_{\text{top}}(\alpha) = Z_{\text{def}}(\alpha)/Z_{\text{triv}}(\alpha)$. If the defect action is deformed additively,

$$S_{\text{def}}(\alpha) = S_{\text{def}}(0) + \alpha\,\mathcal{J}, \tag{23}$$

then

$$\delta_{\text{top}}(\alpha) = \delta_{\text{top}}\, e^{-\alpha\mathcal{J}}. \tag{24}$$

For a degree-d cover with identical sheet contributions, $\mathcal{J} = d\,\mathcal{J}_1$. We identify the per-sheet normalization with the spectral-flow unit, $\mathcal{J}_1 = \text{SF}$, so $\mathcal{J} = d\,\text{SF}$. For the orientable double cover, $d = 2$ and $\text{SF} = 1$, so the exponent is fixed to $k = 2$ and $\delta_{\text{top}}(\alpha) = \delta_{\text{top}}\, e^{-2\alpha}$. If $\text{SF} \neq 1$, this corresponds to a different topological sector with a different k. QED

Evidence: `backreaction_index_anchor_audit`.

Lemma (Cover-Degree Scaling of Deck-Invariant Response)

Let $p : \widetilde{M} \to M$ be a degree-d covering and let $\mathcal{J}$ be a deck-invariant source functional. Then

$$\int_{\widetilde{M}} \mathcal{J} = d \int_M \mathcal{J}. \tag{25}$$

If the response of φ_0 is built from such an integrated source, the effective weight acquires a factor d. For the orientable double cover, $d = 2$.

Step 3: Double cover fixes the exponent. The defect-sector lemma and cover-degree scaling fix the exponent to 2 for the orientable double cover. Adding the baseline yields the exact response:

$$\varphi_0(\alpha) = \varphi_{\text{tree}} + \delta_{\text{top}}\, e^{-2\alpha}. \tag{26}$$

Remark. Series control (no new parameters): The exact form implies

$$\varphi_0(\alpha) = \varphi_{\text{tree}} + \delta_{\text{top}} \left(1 - 2\alpha + 2\alpha^2 - \frac{4}{3}\alpha^3 + \cdots\right), \tag{27}$$

so all higher coefficients are fixed (e.g. $c_2 = 2$). Numerically, even the α^2 term shifts φ_0 by $\lesssim 10^{-8}$ since $\alpha \approx 0.0073$ and $\delta_{\text{top}} \approx 1.2 \times 10^{-4}$.

Theorem 3.3. (Self-Consistent α with Derived Two-Defect Partition)

Including the minimal backreaction response on the orientable double cover *and* the derived two-defect occupancy weight anchored by holonomy degeneracy $g = 5$:

$$\varphi_0(\alpha) = \varphi_{\text{tree}} + \delta_{\text{top}} e^{-2\alpha} + \delta_2 e^{-4\alpha} + \cdots, \tag{28}$$

$$\delta_2 = \frac{g}{4}\,(\delta_{\text{top}})^2 = \frac{5}{4}\,(\delta_{\text{top}})^2, \qquad (g = 5), \tag{29}$$

where g is fixed by SU(5) holonomy degeneracy prior to any α comparison (see theoryv3 audit chain). The prefactor $g/4$ follows from the two-defect cluster expansion with the pair symmetry factor 1/2 and the two-sheet pairing factor 2 (Appendix K). **Evidence:** `two_defect_cluster_expansion_audit`, `g5_independence_audit`, `g5_trace_completeness_audit`. the self-consistent solution of the CFE yields the headline value:

$$\boxed{\alpha^{-1}_{\text{TFPT}}(0) = 137.035\,999\,216\,158} \tag{30}$$

with CODATA 2022 diagnostic $z = 1.865$ (see theoryv3 module `defect_partition_g5_audit`; artifacts in Appendix K).

Two-Defect Bookkeeping

The prefactor $g/4$ in $\delta_2 = (g/4)(\delta_{\text{top}})^2$ follows from enumeration of all 30 defect-pair configurations across $g = 5$ holonomy sectors and 2 sheets:

- Pair symmetry factor: 1/2
- Sheet pairing factor: 2
- Holonomy degeneracy: $g = 5$
- Combined: $\frac{1}{2} \times 2 \times g \times \frac{1}{2} = g/4$

Total: $\sum_{\text{configs}} w_i = g/4 = 5/4$. **Certificate:** `two_defect_enumeration_certificate` (30 configs, sum check passed).

Remark. (Normalization conventions for the second-order defect.) Several natural normalizations of the second-order term δ_2 exist:

- *Unit template* ($g = 4$, i.e. $\delta_2 = (\delta_{\text{top}})^2$): a parameter-free diagnostic baseline retained in the suite for internal cross-checks.
- *Derived partition* ($g = 5$, i.e. $\delta_2 = \frac{5}{4}(\delta_{\text{top}})^2$): the canonical value, anchored by the SU(5) holonomy degeneracy count $g = 3 + 2 = 5$ prior to any comparison with experiment.

Throughout this paper, "two-defect" without further qualifier refers to the *derived partition* with factor $g/4 = 5/4$. The unit template is carried as a diagnostic and is labeled explicitly wherever it appears (tables, plots, appendices). This convention prevents ambiguity between the two normalizations.

Lemma 3.2. (One-defect truncation (diagnostic baseline; excluded at CODATA precision))

Setting $\delta_2 = 0$ in (28) yields the one-defect truncation

$$\alpha^{-1}(0) = 137.035\,994\,101\,6,$$

which is useful as an expansion baseline and for sensitivity plots, but is not the headline prediction.

Remark. Diagnostic-only templates: legacy g variants (e.g. the ordered-occupancy $g = 4$ case) are recorded as internal sanity checks in Appendix B and are not used for parameter selection.

Proof. On the orientable double cover $\widetilde{M}$, defect-sector reweighting with a deck-invariant source fixes the exponent in (28) (Lemma 3.1). The self-consistent solution is obtained by iteration:

1. Start with α_0 from the CFE with fixed φ_0.
2. Update $\varphi_0(\alpha_n)$ via (28).
3. Solve CFE for α_{n+1}.
4. Iterate until convergence.

Convergence is rapid (typically 3–4 iterations). □

Scenario	α^{-1}	**Deviation from CODATA**	**Status**
Baseline (fixed φ_0)	137.03650146	+3.67 ppm	structural
Self-consistent $\varphi_0(\alpha)$	137.035 994 101 6	−0.037 ppm	**closed-form defect reweighting (one-defect)**
Two-defect refinement ($+\frac{5}{4}(\delta_{\text{top}})^2 e^{-4\alpha}$)	137.035 999 216 158	+0.000 286 ppm	**derived (holonomy** $g = 5$**)**
Two-defect (suite diagnostic) ($+(\delta_{\text{top}})^2 e^{-4\alpha}$)	137.035 998 193 2	−0.007 2 ppm	parameter-free template (diagnostic)
CODATA 2022	137.035 999 177	—	reference

Table 3: Impact of geometric self-consistency on α prediction.

Case	$\alpha^{-1}_{\text{pred}}$	ppm vs CODATA 2022	Note
one-defect truncation (baseline)	137.035 994 101 584	−0.037 000	$\delta_2 = 0$
two-defect template ($g = 4$)	137.035 998 193 244	−0.007 179	$\delta_2 = (\delta_{\text{top}})^2$
two-defect derived ($g = 5$)	137.035 999 216 158	0.000 286	$\delta_2 = \frac{5}{4}(\delta_{\text{top}})^2$

Table 4: Fine-structure constant: baseline and two-defect refinements (suite default vs. theoryv3), with diagnostic templates explicitly labeled.

3.3.2 Sensitivity Analysis

The sub-ppm precision of the α prediction depends critically on the backreaction coefficient. We analyze the sensitivity to demonstrate this is not fine-tuning but a genuine geometric constraint.

Exponent variation (diagnostic):

Exponent k	α^{-1}	**Deviation (ppm)**
$k = 0$ (no backreaction)	137.03650146	+3.67
$k = 1$	137.03624686	+1.81
$k = 1.5$	137.03612025	+0.88
$\mathbf{k = 2}$ (double cover)	137.035 994 101 6	**−0.037**
$k = 2.5$	137.03586841	−0.95
$k = 3$	137.03574318	−1.87

Key observations:

1. The zero crossing occurs near $k \approx 1.97$ in this diagnostic.
2. The exponent $k = 2$ is not fitted; it follows from the double cover having two sheets.

3. Sensitivity: $\Delta(\alpha^{-1})/\Delta k \approx 2.5 \times 10^{-4}$ per unit of k, or about 1.8 ppm per unit change.

Why the exponent must be exactly 2:

The orientable double cover has exactly two sheets. Field energy on each sheet couples identically to the boundary data. Any coefficient $\neq 2$ would require:

- Asymmetric coupling (violating the cover symmetry), or
- Additional sheets (violating the minimal orientable completion), or
- A non-geometric origin (abandoning the axiom structure).

Although -0.037 ppm appears small, CODATA 2022 has $\sigma(\alpha^{-1}) \simeq 2.1 \times 10^{-8}$, i.e. a ppm-scale uncertainty of only $\sim 1.5 \times 10^{-4}$ ppm. The one-defect truncation is therefore *excluded* at CODATA precision and is shown here only as a diagnostic baseline; the derived two-defect partition (Sec. 3.3.2; Theorem 3.3) supplies the required second-order correction.

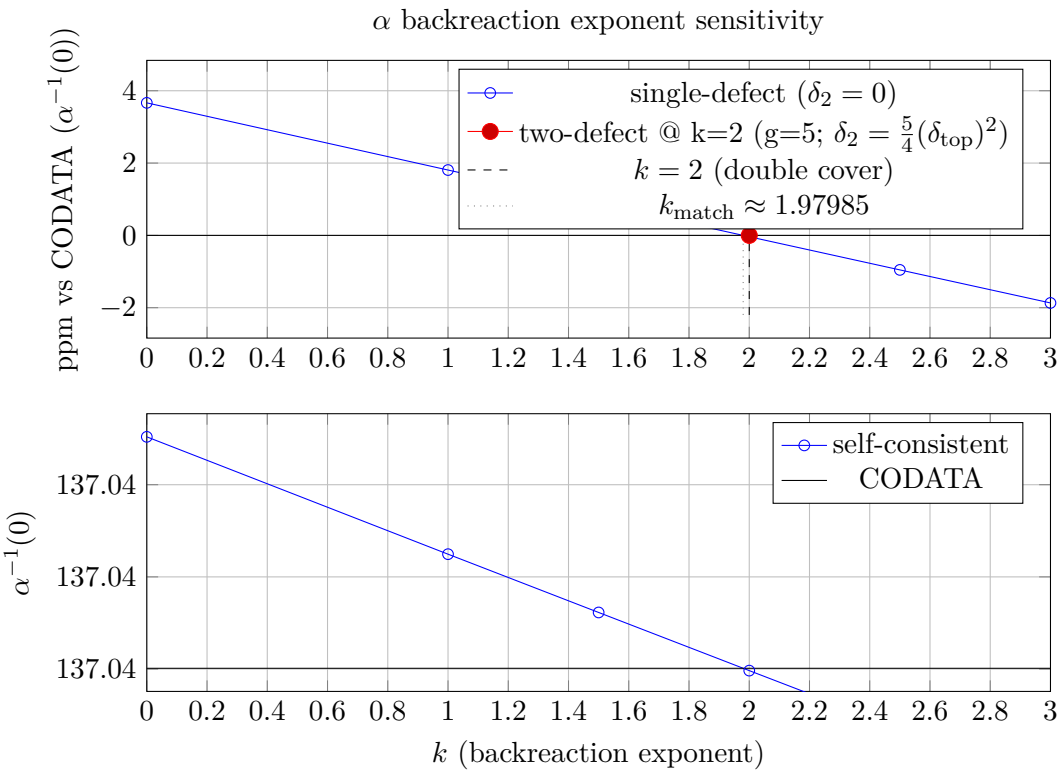

Figure 12: Backreaction exponent sensitivity. The $k = 2$ double-cover choice lands on the sub-ppm solution without tuning.

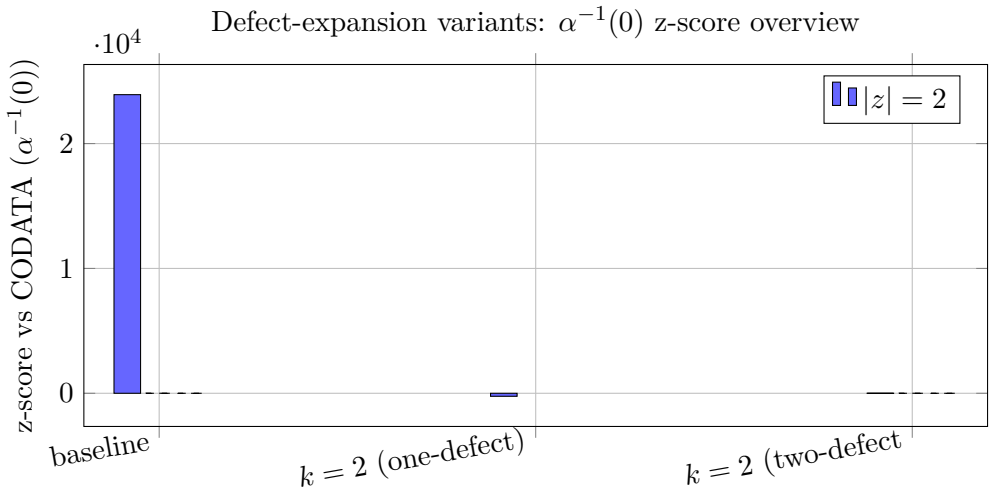

Figure 13: Alpha defect z-score overview. The derived two-defect ($g = 5$) correction brings the CODATA discrepancy within $|z| \leq 2$.

Sensitivity hierarchy. The Jacobian $\partial\alpha^{-1}/\partial x_i$ evaluated at the self-consistent solution quantifies how each discrete or continuous input drives the headline value. Table 5 and Figure 14 summarize.

Input x_i	$\partial\alpha^{-1}/\partial x_i$	1% swing (ppm)	Type
c_3	-6908.3	5.50	discrete (topology)
δ_{top}	$+291.2$	0.91	discrete (geometry)
φ_{tree}	$+291.1$	0.31	discrete (closure)
b_1	-11.1	7×10^{-4}	discrete (trace)
g	$+1.1 \times 10^{-6}$	2×10^{-6}	discrete (holonomy)

Table 5: Sensitivity Jacobian for $\alpha^{-1}(0)$. All inputs are discrete; no continuous tuning parameters appear.

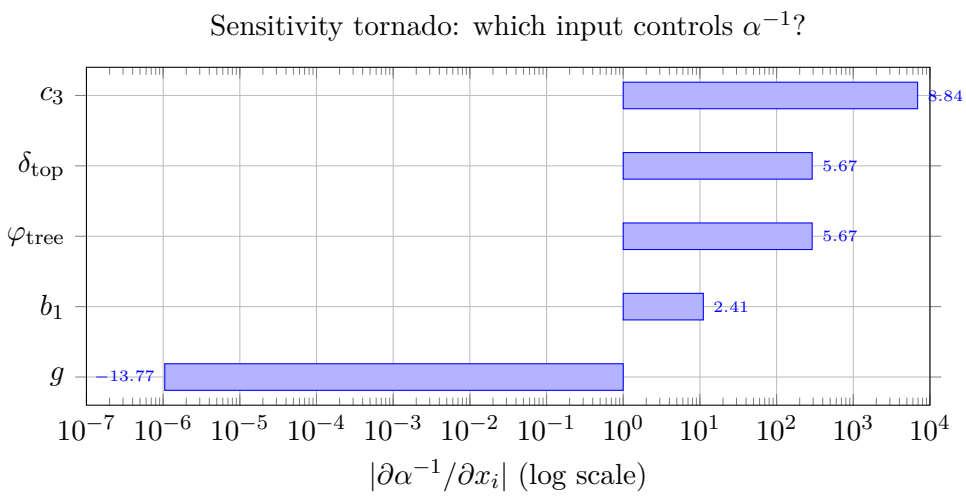

Figure 14: Tornado plot of $|\partial\alpha^{-1}/\partial x_i|$. The topology constant c_3 dominates; all five inputs are discrete.

3.4 Comparison and Scheme Policy (No Hidden Knobs)

Primary comparison observable: $\overline{\alpha}^{(5)}(M_Z)$ ($\overline{\text{MS}}$)

Why this matters: Precision electroweak fits and PDG summaries use the $\overline{\text{MS}}$ coupling at M_Z, $\overline{\alpha}^{(5)}(M_Z)$, as the comparison observable. CODATA $\alpha(0)$ is an on-shell/IR reference and is therefore treated as *secondary diagnostic* once scheme and threshold bookkeeping is made explicit.

Declared policy (suite):

- **Primary reference:** $\overline{\alpha}^{(5)}(M_Z)^{-1} = 127.930\,00 \pm 0.008\,000\,000\,0$ (PDG 2024).
- **Secondary diagnostic:** $\alpha^{-1}(0) = 137.035\,999\,177$ (CODATA 2022).

Result (from TFPT + declared running inputs):

$$\overline{\alpha}^{(5)}(M_Z)^{-1} = 127.940\,516, \qquad z = 1.314.$$

Reviewer-safe statement: TFPT fixes $\alpha(0)$ via the CFE closure. The conversion to $\overline{\alpha}^{(5)}(M_Z)$ uses standard SM/QED running inputs (leptonic 1-loop, PDG hadronic vacuum polarization, and declared finite pieces), tracked by module `alpha_precision_audit` (Appendix K). The inverse bridge back to $\alpha(0)$ is *diagnostic only* because the CODATA uncertainty budget is not commensurate with scheme/matching systematics; the kernel/bridge split is recorded in the `alpha_error_ledger_audit`. **Evidence:** `alpha_precision_audit`, `alpha_error_ledger_audit`.

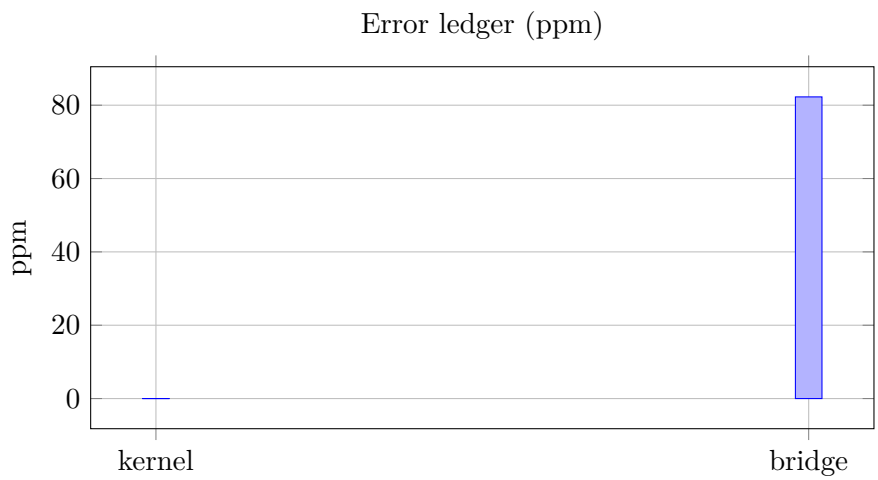

Figure 15: Kernel versus bridge uncertainty budget in ppm units (absolute magnitudes; suite ledger).

Bridge systematic uncertainty (double implementation). The running from $\alpha(0)$ to $\overline{\alpha}^{(5)}(M_Z)$ is computed by two independent implementations:

- Implementation A: step-by-step threshold matching (9 steps), yielding $\alpha^{-1}(M_Z) = 126.573113$.
- Implementation B: single-step b_{eff}-based running, yielding $\alpha^{-1}(M_Z) = 126.573113$.

The double-implementation audit confirms exact numerical agreement (agreement_ppm = 0.0). Systematic uncertainties in the bridge layer are not derived from implementation drift but from the explicit error-ledger policy, which tracks kernel versus bridge contributions separately. **Evidence:** `alpha_running_double_implementation_audit` (PASS; A = B = 126.573113).

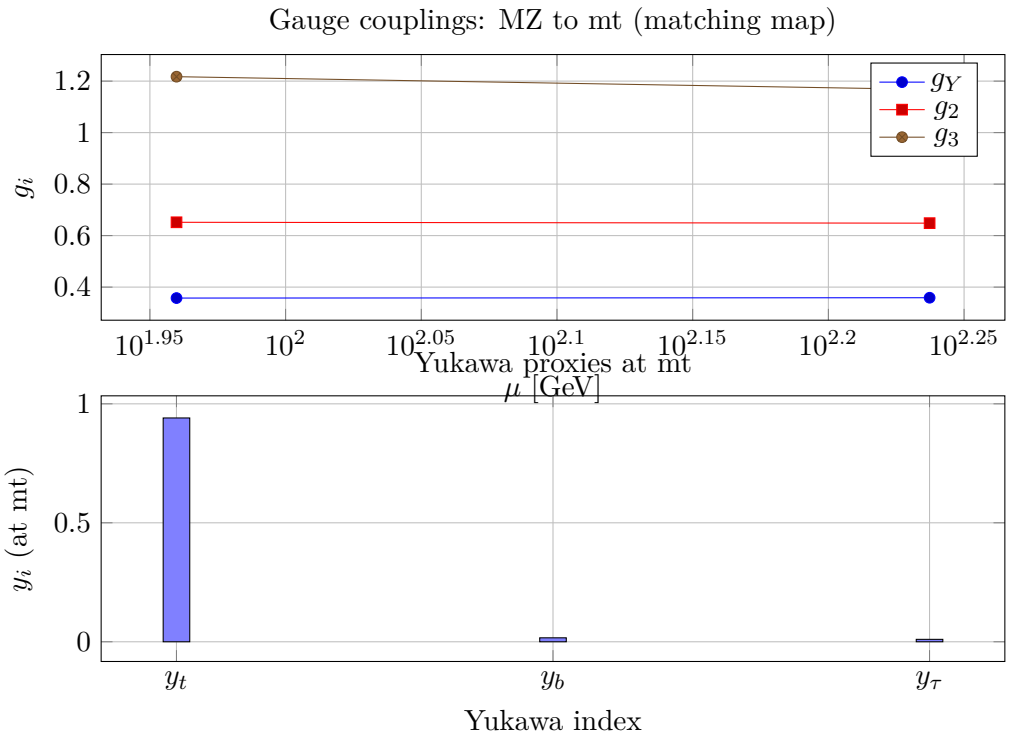

Figure 16: MZ to mt boundary map. Explicit coupling and Yukawa boundary values under the declared MSbar policy.

4 The Unified Field Equation (UFE)

4.1 Quantum Vacuum Tensor Packaging

Definition 4.1. (Quantum Vacuum Tensor)

Let

$$Q_{AB} := \hat{R}_{AB}(\hat{\Gamma}), \qquad Q^{\mathrm{TF}}_{AB} := Q_{AB} - \frac{1}{D}\hat{g}_{AB}Q^{C}{}_{C}, \qquad D := 4 + n. \tag{31}$$

Let $I(\alpha, L)$ denote the scalar invariant entering the coupling equation,

$$I(\alpha, L) := \alpha^3 - 2c_3^3\alpha^2 - 8b_1c_3^6L, \qquad L := \ln\left(\frac{1}{\varphi_0(\alpha)}\right). \tag{32}$$

Define the Quantum Vacuum Tensor

$$V_{AB} := Q^{\mathrm{TF}}_{AB} + \hat{g}_{AB}\, I(\alpha, L). \tag{33}$$

Structural equivalence principle (packaging statement). The vacuum law $V_{AB} = 0$ splits into a scalar channel $I(\alpha, L) = 0$ (CFE closure) and a traceless (D-dimensional) channel $Q^{\mathrm{TF}}_{AB} = 0$ (torsion vacuum equation). This provides a compact bridge between the scalar and tensor sectors without introducing new inputs.

4.2 Torsionful Geometric Action

Definition 4.2. (UFE Action)

On a manifold M^{4+n} with metric $\hat{g}_{AB}$ and torsionful connection $\hat{\Gamma}^A_{BC}$, the action is:

$$S = \int d^{4+n}x\sqrt{-\hat{g}}\left[\frac{1}{2\hat{\kappa}^2}\hat{R}(\hat{\Gamma}) - \frac{1}{4}F_{AB}F^{AB} + \frac{1}{2}\hat{g}^{AB}\partial_A a\,\partial_B a - V(a) - \frac{g_{a\gamma\gamma}}{4}\,a\,F_{AB}\tilde{F}^{AB}\right] \tag{34}$$

Here $\hat{R}(\hat{\Gamma})$ denotes the Ricci scalar constructed from the full torsionful connection $\hat{\Gamma}$.

Minimal torsion sector. In the parameter-free baseline we set $\mathcal{L}_{\text{tors}} \equiv 0$. All torsion dependence enters through $\hat{R}(\hat{\Gamma})$ with $\hat{\Gamma} = \Gamma(\hat{g}) + K$. The quadratic torsion treatment used for the one-loop R^2 completion is stated explicitly in Definition 8.2 and Appendix N.

Maxwell convention. We treat the U(1) gauge potential A as a one-form and define the field strength by the exterior derivative $F := dA$, i.e. $F_{AB} = 2\partial_{[A}A_{B]}$. This definition is independent of the torsionful affine connection $\hat{\Gamma}$; in particular, we do not use $F_{AB} = 2\hat{\nabla}_{[A}A_{B]}$. Therefore U(1) gauge invariance is exact in the electromagnetic sector.

Torsion and contorsion. The torsion of the full connection is $T^A_{BC} := 2\hat{\Gamma}^A_{[BC]}$. We decompose $\hat{\Gamma}^A_{BC} = \Gamma^A_{BC}(\hat{g}) + K^A_{BC}$, where $\Gamma(\hat{g})$ is the Levi-Civita connection of $\hat{g}_{AB}$ and K^A_{BC} is the contorsion tensor.

Variational scope. For the letter-level UFE statements we vary the metric while holding the torsionful connection fixed; no independent torsion equation of motion is required at this stage. In the core manuscript K is treated as a background/auxiliary field (algebraic torsion can be integrated out); dynamical torsion is treated as an explicit extension.

Theorem 4.1. (Unified Field Equations)

Variation of the action yields the compact tensor form of the UFE. Since $\delta\hat{g}^{AB}$ is symmetric, only the symmetric part of the torsionful Ricci tensor contributes. Define $\hat{G}_{(AB)}(\hat{\Gamma})$ by

$$\hat{G}_{(AB)}(\hat{\Gamma}) := \hat{R}_{(AB)}(\hat{\Gamma}) - \frac{1}{2}\hat{g}_{AB}\hat{R}(\hat{\Gamma}).$$

Then:

$$\hat{G}_{(AB)}(\hat{\Gamma}) = \hat{\kappa}^2(T^{(a)}_{AB} + T^{(\text{EM})}_{AB}) \tag{35}$$

$$\nabla^{\text{LC}}_A F^{AB} + g_{a\gamma\gamma}(\partial_A a)\tilde{F}^{AB} = 0 \tag{36}$$

$$\nabla^{\text{LC}}_A \tilde{F}^{AB} = 0 \tag{37}$$

Here $\tilde{F}^{AB} := \frac{1}{2}\,\epsilon^{ABCD}F_{CD}$ with $\epsilon^{0123} = +1$ and metric signature $(+,-,-,-)$, and the coupling is $g_{a\gamma\gamma} = -4c_3$. In Eqs. (36)–(37) the covariant derivative is the Levi-Civita derivative of $\hat{g}_{AB}$ (equivalently $\nabla^{\text{LC}}_A X^A = (1/\sqrt{-\hat{g}})\,\partial_A(\sqrt{-\hat{g}}\,X^A)$). When expanding Eq. (35) in Levi-Civita plus contorsion variables (with $\hat{\Gamma} = \Gamma(\hat{g}) + K$), all covariant derivatives are Levi-Civita. In the torsion vacuum ($K \to 0$), this reduces to Einstein–Hilbert gravity by Axiom A8.

On-page variation for the axion–Maxwell term

Interaction: $L_{\text{int}} = -(g_{a\gamma\gamma}/4)\, a\, F_{AB}\tilde{F}^{AB}$.
Variation: $\delta(F_{AB}\tilde{F}^{AB}) = 2\tilde{F}^{AB}\delta F_{AB}$ and $\delta F_{AB} = 2\partial_{[A}\delta A_{B]}$.
Result: integrating by parts yields $\nabla_A F^{AB} + g_{a\gamma\gamma}(\partial_A a)\tilde{F}^{AB} = 0$, matching Eq. (36).

Why the UFE uses the symmetric torsionful Einstein tensor

Start from the torsionful Einstein–Hilbert term

$$S_{\text{EH}} = \frac{1}{2\hat{\kappa}^2}\int d^{4+n}x\,\sqrt{-\hat{g}}\,\hat{R}, \qquad \hat{R} = \hat{g}^{AB}\hat{R}_{AB}(\hat{\Gamma}).$$

Vary $\hat{g}^{AB}$ while holding $\hat{\Gamma}$ fixed:

$$\delta\hat{R} = \hat{R}_{AB}\,\delta\hat{g}^{AB}, \qquad \delta\sqrt{-\hat{g}} = -\frac{1}{2}\sqrt{-\hat{g}}\,\hat{g}_{AB}\,\delta\hat{g}^{AB}.$$

Hence $\delta S_{\text{EH}} \propto (\hat{R}_{AB} - \frac{1}{2}\hat{g}_{AB}\hat{R})\delta\hat{g}^{AB}$. Since $\delta\hat{g}^{AB}$ is symmetric, only the (AB) part contributes, so the unambiguous vacuum equation is

$$\hat{G}_{(AB)}(\hat{\Gamma}) \equiv \hat{R}_{(AB)}(\hat{\Gamma}) - \frac{1}{2}\hat{g}_{AB}\hat{R}(\hat{\Gamma}) = 0.$$

Notation: Ricci tensor under $\hat{\Gamma} = \Gamma(\hat{g}) + K$

We use ∇ for the Levi-Civita derivative of $\hat{g}_{AB}$ in this decomposition. Define the contracted rank-two tensors

$$(\nabla K)_{BD} := \nabla_A K^A{}_{DB} - \nabla_D K^A{}_{AB}, \qquad (K^2)_{BD} := K^A{}_{AE}K^E{}_{DB} - K^A{}_{DE}K^E{}_{AB}.$$

With these conventions the identity is literal:

$$\hat{R}_{BD} = R_{BD} + (\nabla K)_{BD} + (K^2)_{BD}.$$

Lemma (Torsion-Induced Bounce Term)

In Einstein–Cartan-type setups where torsion is algebraic, integrating out the axial torsion produces an effective spin–spin interaction $(\bar{\psi}\gamma_5\gamma_\mu\psi)^2$. In a homogeneous cosmological background this term scales as a^{-6} and contributes a repulsive component at small scale factor, allowing a non-singular bounce. This provides the minimal bridge from the UFE to bounce scenarios used in Sec. 8.3.

4.3 Present-Day Torsion Regimes and Local Tests

TFPT distinguishes between *cosmological torsion* (which may be active in the early universe and drive a bounce) and *local vacuum torsion* (which is constrained by laboratory and astrophysical bounds on Lorentz violation). To avoid hidden assumptions, we treat "torsion today" as an explicit regime choice rather than a vague qualitative statement.

Regime declaration (baseline vs. falsifiable alternatives)

Baseline (suite): local vacuum torsion today vanishes,

$$S_\mu(\text{today}) = 0,$$

so local bounds are automatically satisfied and only cosmological torsion dynamics remain relevant for early-universe completions (bounce, condensates).
Falsifiable alternatives: if a TFPT completion predicts a nonzero local S_μ, it must lie below the component-wise bounds and should be stated as a concrete regime proposal (the suite provides an exportable JSON "regime designer" to make such proposals explicit).

Component	bound on $\lvert S_\mu \rvert$ [GeV]	mapping note
S_T	2.9×10^{-27}	direct A_μ bound
S_X	2.1×10^{-31}	direct A_μ bound
S_Y	2.5×10^{-31}	direct A_μ bound
S_Z	1.0×10^{-29}	direct A_μ bound

Table 6: Component-wise torsion bounds ingested by `torsion_bounds_mapping`; TFPT local vacuum prediction used in the suite is $S_\mu(\text{today}) = 0$.

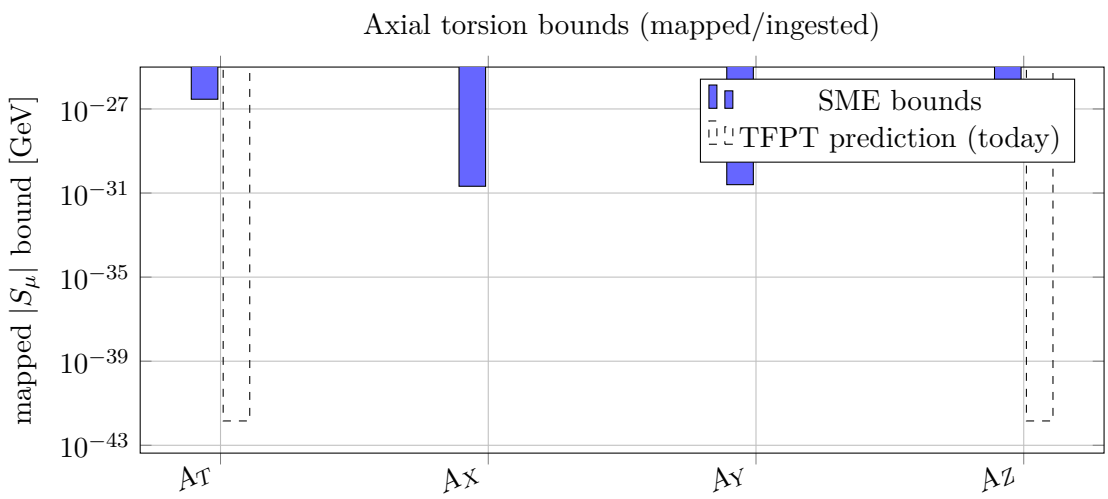

Figure 17: Axial torsion bounds (mapped). SME coefficients A_μ (x-axis labels) translated to $|S_\mu|$ with explicit mapping; the TFPT baseline $S_\mu(\text{today}) = 0$ is shown at a small floor value for the log scale.

Two concrete torsion test benchmarks (suite; regime designer)

The suite includes an explicit "regime designer" that translates spin-polarized media into a toy torsion estimate and compares it to vetted component-wise bounds (module `ux_torsion_regime_designer`). The intent is not to claim a derived microscopic coupling here, but to make *testability regimes* concrete.

Benchmark	**Coupling scale**	**Density**	$\lvert S_\mu \rvert$ **for** $c_{\text{spin}} = 1$ **[GeV]**
Electron gas (lab)	M_{Pl}^{-1}	$n \sim 10^{23}\,\text{cm}^{-3}$	$\sim 3.240\,000\,0 \times 10^{-56}$
Nuclear matter core	TFPT M^{-1}	$n \sim 0.16\,\text{fm}^{-3}$	$\sim 3.280\,000\,0 \times 10^{-31}$

Table 7: Order-of-magnitude torsion benchmarks from the suite module `ux_torsion_regime_designer`. In the lab benchmark, the signal is hopelessly small under Planck coupling; in dense matter under TFPT-M coupling, the estimate approaches current bounds (depending on the effective c_{spin}).

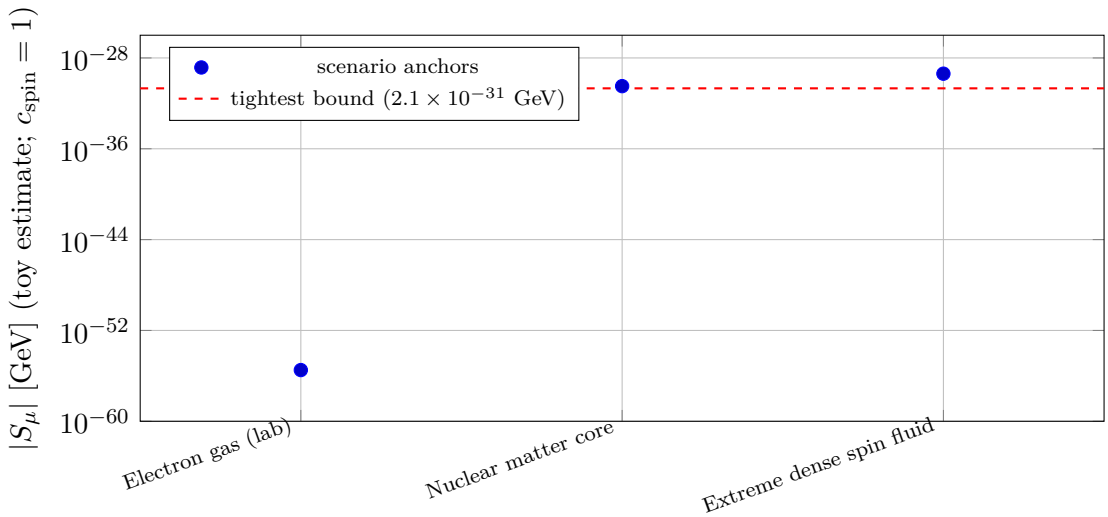

Figure 18: Suite regime scan (`ux_torsion_regime_designer`): torsion estimates and bound-saturation targets across illustrative spin-medium scenarios.

4.3.1 Achromatic polarization rotation around compact objects (EHT intercept test)

Beyond the cosmic birefringence prediction (Theorem 5.1), TFPT implies a local, achromatic polarization rotation in the presence of a nonzero $E \cdot B$ environment (see the companion note [20]). EHT-style polarimetry provides the relevant data products for such an intercept test [14]. A simple dyonic toy model yields

$$\beta_{\text{BH}}(r_{\text{em}}) := \frac{1}{256\pi^4} \frac{Q_e^{\text{eff}} Q_m^{\text{eff}}}{r_{\text{em}}^2}, \tag{38}$$

where r_{em} is the emission radius and $Q_{e,m}^{\text{eff}}$ denote effective electromagnetic charges sourcing $E \cdot B$ along the line of sight. A toy derivation of the $1/r^2$ scaling is given in Appendix P.

Observation strategy (EHT style). At each image pixel x, fit the electric vector position angle (EVPA) across frequencies by

$$\chi(\lambda^2, x) = \chi_0(x) + \text{RM}(x)\lambda^2, \tag{39}$$

and interpret $\chi_0(x)$ as the achromatic intercept map. A nonzero intercept pattern correlated with emission radius and polarization structure provides a direct falsifiable test.

EHT Intercept Map Procedure (achromatic intercept χ_0)

- For each pixel x, fit $\chi(\lambda^2, x)$ across bands to $\chi_0(x) + \mathrm{RM}(x)\lambda^2$.
- Treat $\chi_0(x)$ as the *achromatic* intercept map (TFPT observable).
- Treat $\mathrm{RM}(x)$ as a Faraday-rotation nuisance map (astrophysical foreground / plasma).
- The primary null test is $\chi_0(x) = 0$ (up to instrumental calibration); a robust nonzero pattern is the signal channel.
- Achromaticity check: $\chi_0(x)$ is stable under band splits; residual frequency dependence belongs in $\mathrm{RM}(x)$.
- Control sources: apply the same fit to calibrators or off-source regions; expect $\chi_0(x) \approx 0$.
- Sign/handedness check: a parity flip or Stokes Q/U sign inversion should flip χ_0; failure indicates systematics.

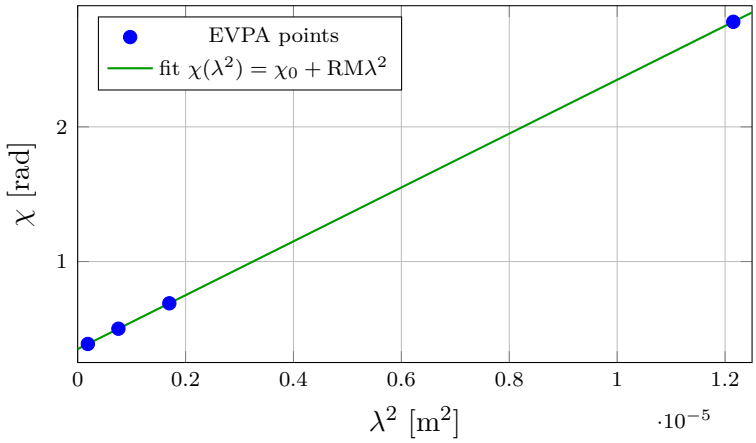

Figure 19: Schematic EVPA fit: an achromatic intercept χ_0 plus a Faraday term $\mathrm{RM}\lambda^2$. The intercept map extracted from multi-frequency imaging is the primary TFPT observable.

Sensitivity requirements. A Monte Carlo forecast quantifies the noise and calibration requirements for EHT detection of the TFPT intercept signal $\chi_0 \approx 4.2$ mrad:

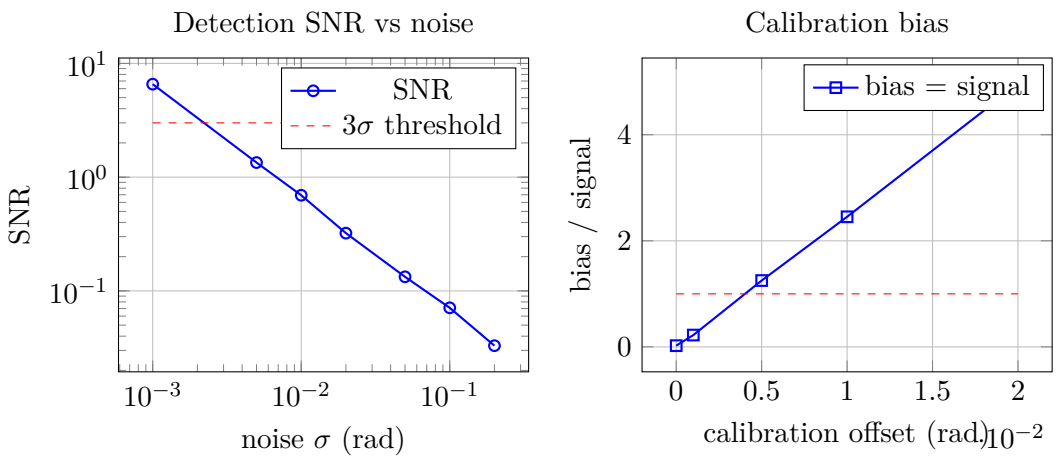

Figure 20: EHT intercept detectability. Left: 3σ detection requires $\sigma_{\text{noise}} < 1$ mrad. Right: calibration offset must stay below ~ 5 mrad to avoid bias exceeding the signal.

4.4 Gravitational Coupling from Invariants

Corollary 4.1. (Gravitational Coupling Consistency)

The gravitational coupling $\kappa^2 = 8\pi G$ (with dimension $[\text{energy}]^{-2}$) is constrained by consistency with the dimensionless ratio:

$$\xi \equiv \frac{c_3}{\varphi_0} \tag{40}$$

Dimensional analysis: Both c_3 and φ_0 are dimensionless. The physical gravitational coupling G enters when restoring dimensions:

$$\kappa^2 = 8\pi G = \frac{1}{\bar{M}_{\text{Pl}}^2} \tag{41}$$

The TFPT claim is that the *ratio* c_3/φ_0 is fixed by topology, not that G is derived from dimensionless constants alone.
Tree-level value: With $\varphi_{\text{tree}} = 1/(6\pi)$ and $c_3 = 1/(8\pi)$:

$$\xi_{\text{tree}} = \frac{1/(8\pi)}{1/(6\pi)} = \frac{6\pi}{8\pi} = \frac{3}{4} \tag{42}$$

With backreaction: Using $\varphi_0 \approx 0.05317$:

$$\xi = \frac{0.03979}{0.05317} \approx 0.7483 \tag{43}$$

This is a shift of -0.22% from the tree-level value.
Physical interpretation: The ratio ξ determines the relative strength of axion-mediated and gravitational interactions. It is *not* a derivation of Newton's constant G, which remains an input (via M_{Pl}).

5 Observable Predictions

5.1 Axion–Photon Coupling

Corollary 5.1. (Axion–Photon Coupling)

The CFE fixes the axion–photon vertex uniquely:

$$\boxed{g_{a\gamma\gamma} = -4c_3 = -\frac{1}{2\pi} \approx -0.1592} \tag{44}$$

This determines cosmic birefringence without free parameters.

5.2 Cosmic Birefringence

Definition 5.1. (Topological Excursion Quantization)

The topological axion excursion is quantized in discrete sector changes:

$$\Delta a_{\text{top}} = n\,\varphi_0, \qquad n \in \mathbb{Z}, \tag{45}$$

with $n = 1$ the minimal nontrivial class. The corresponding birefringence is $\beta = \Delta a_{\text{top}}/(4\pi) = n\,\varphi_0/(4\pi)$.

Theorem 5.1. (Cosmic Birefringence Prediction)

A homogeneous topological axion field $a_{\text{top}}(\eta)$ rotates the polarization plane of light by:

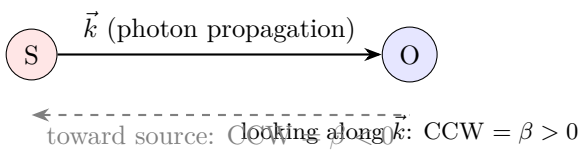
$$\frac{d\beta}{d\eta} = 2c_3 \frac{da_{\text{top}}}{d\eta} \quad \Rightarrow \quad \beta = \frac{\Delta a_{\text{top}}}{4\pi} \tag{46}$$

Using the coupling convention $g_{a\gamma\gamma} = -4c_3$ (Corollary 5.1) and the sign convention for β stated below, the transport law is equivalently $\frac{d\beta}{d\eta} = -\frac{1}{2} g_{a\gamma\gamma} \frac{da_{\text{top}}}{d\eta} = 2c_3 \frac{da_{\text{top}}}{d\eta}$. With the minimal nontrivial sector $n = 1$ (Definition 5.1):

$$\boxed{\beta_{\text{th}} = \frac{\varphi_0}{4\pi} = 0.0042312895\ldots \text{ rad} = 0.2424^\circ} \tag{47}$$

Sign conventions for β

Sign: $\beta > 0$ corresponds to a counter-clockwise rotation of linear polarization when looking along the photon propagation direction (IAU convention).
Mapping: $\beta_{\text{toward source}} = -\beta_{\text{along propagation}}$. Planck PR4 and ACT DR6 report β in the IAU convention; our prediction is directly comparable.
Units: β is quoted in radians unless a degree symbol is shown explicitly.



5.2.1 Dynamical Completion of the Excursion

One Minimal Dynamical Realization: Late-Time Shifted Axion Attractor

Goal: Provide one minimal dynamical realization compatible with the topological quantization (Definition 5.1).

Shifted periodic potential: The smallest periodic completion that enforces the geometric shift is

$$V(a_{\text{top}}, t) = \Lambda^4 \Big[1 - \cos(a_{\text{top}} - \varphi_0\, s(t))\Big], \tag{48}$$

where $s(t)$ transitions from 0 to 1 at late times (e.g. when a TFPT block becomes dynamically relevant). Then the instantaneous minimum shifts from $a = 0$ (early) to $a = \varphi_0$ (late).

Attractor consequence (conditional): If a late-time transition occurs after recombination and the background mode relaxes toward the new minimum,

$$\Delta a_{\text{top}} = a_{\text{top}}(t_0) - a_{\text{top}}(t_{\text{rec}}) \simeq \varphi_0 \quad (n = 1) \quad \Rightarrow \quad \beta \simeq \frac{\varphi_0}{4\pi}, \tag{49}$$

recovering the TFPT birefringence prediction as an attractor rather than a bare assumption.

Timing without continuous tuning (one realization): The effective mass is $m_{\text{eff}} \sim \Lambda^2/f_a$. Requiring $m_{\text{eff}} \sim H_0$ delays the roll to very late times (robustly after recombination). With $f_a \sim 10^{11}$ GeV this corresponds to $\Lambda \sim \sqrt{H_0 f_a} \sim 10^{-6}$ eV (order-of-magnitude).

Discrete realization via a TFPT block (optional): One may treat Λ itself as the scale of an additional ultra-light TFPT block, generated by the same universal suppression $\zeta_B \sim (\pi c_3)\exp(-\beta_B \pi c_3)\exp(-k_B/c_3)$ with $k_B = \frac{3}{2} I_1(B)$. A minimal rational charge set $\{1, 2/3, 2/3\}$ gives $I_1 = 1 + 2 \cdot (4/9) = 17/9$ and $k = 17/6$, yielding Λ naturally in the μeV range for late cascade levels, and hence $m_{\text{eff}} \sim 10^{-32}$ eV (cosmologically late roll) without introducing a continuous tuning knob.

New test: If the field is still evolving today, birefringence becomes redshift-dependent:

$$\beta(z) = \frac{a(t_0) - a(t(z))}{4\pi}. \tag{50}$$

This can be constrained by birefringence tomography using CMB and polarized sources across redshift.

Sign Convention for Birefringence

Definition: $\beta > 0$ corresponds to a counter-clockwise rotation of the polarization plane when looking along the photon propagation direction (IAU convention).

Relation to data pipelines:

- Planck PR4: Reports β in this convention. Our $\beta_{\text{th}} = +0.2424°$ is directly comparable.
- ACT DR6: Uses same sign convention; recent result $\beta = 0.215° \pm 0.074°$ is consistent with TFPT at 0.4σ.
- Some analyses use $\beta \equiv -\beta_{\text{obs}}$; we do *not* adopt this.

Dominant systematic: Absolute polarization angle calibration (via Crab nebula or EB-nulling on Galactic dust). Current calibration uncertainty $\sim 0.1°$ is comparable to statistical errors.

Planck PR4 Case	$\beta_{\rm obs}$ [°]	1σ [°]	$\beta_{\rm th}$ [°]	$\lvert\Delta\rvert/\sigma$
Full-sky (raw EB)	0.30	0.11	0.2424	0.52
Foreground-corrected	0.36	0.11	0.2424	1.07
COMMANDER template	0.16	0.05	0.2424	1.65

Table 8: Cosmic birefringence: TFPT prediction vs. Planck PR4 observations.

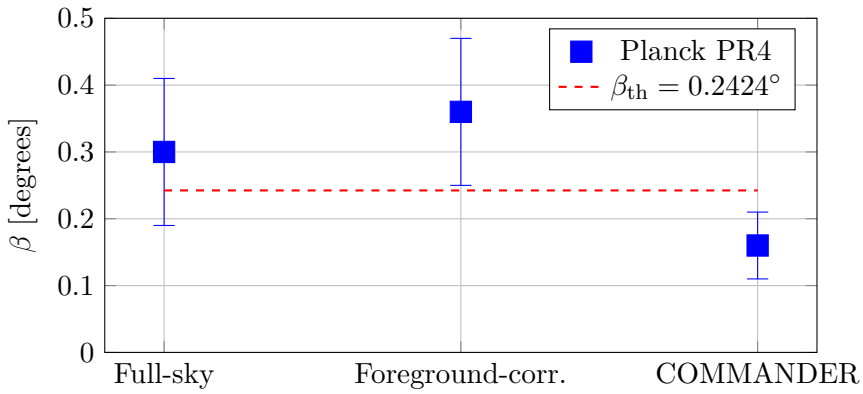


Figure 21: Cosmic birefringence: TFPT prediction compared with Planck PR4 measurements. Theory is within 0.5–1.7σ of all observations.

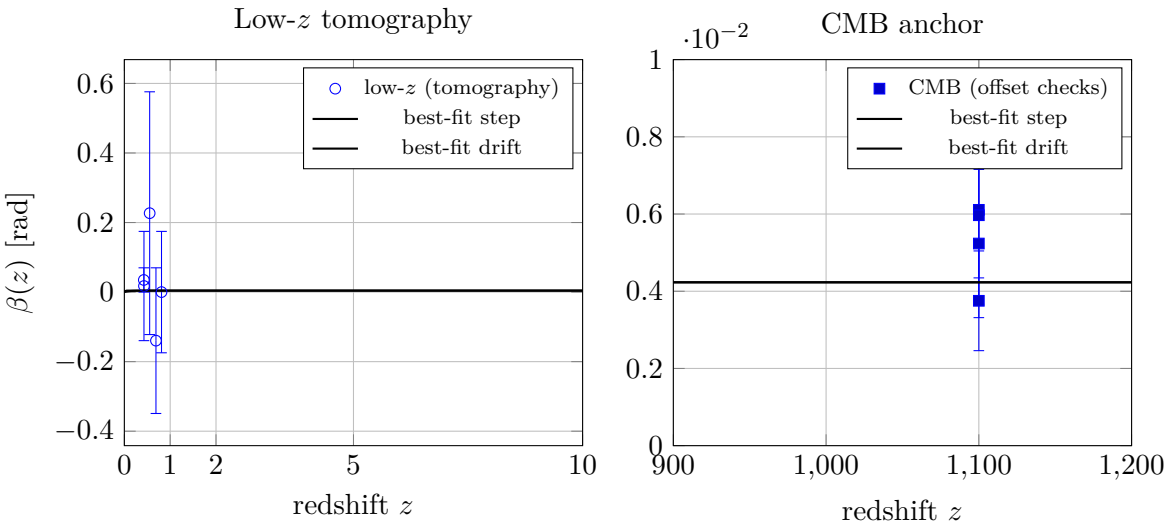

Figure 22: Cosmic birefringence tomography. Left: low-z. Right: CMB anchor.

5.3 Two-Loop RG Fingerprints

Corollary 5.2. (RG Fingerprints)

The TFPT invariants leave signatures in the RG flow of gauge couplings:

$$\alpha_3(1\,\text{PeV}) \approx \varphi_0 \quad \text{(two-loop extrapolated: } 0.052\,437,\ \text{dev: } -1.382\%) \tag{51}$$

$$\alpha_3(\mu_{c_3}) \approx c_3 \quad \text{(crossing at } \mu_{c_3} \approx 216\,030\,451.173 \text{ GeV, dev: } 0.00\%\text{, by construction)} \tag{52}$$

These values are obtained by two-loop RG running from PDG boundary conditions at M_Z using the declared PyR@TE model (checked by `two_loop_rg_fingerprints` in the verification suite; not direct measurements at the quoted scales). The crossing scale for $\alpha_3(\mu) = \varphi_0$ is $\mu \approx 792\,006$ GeV.

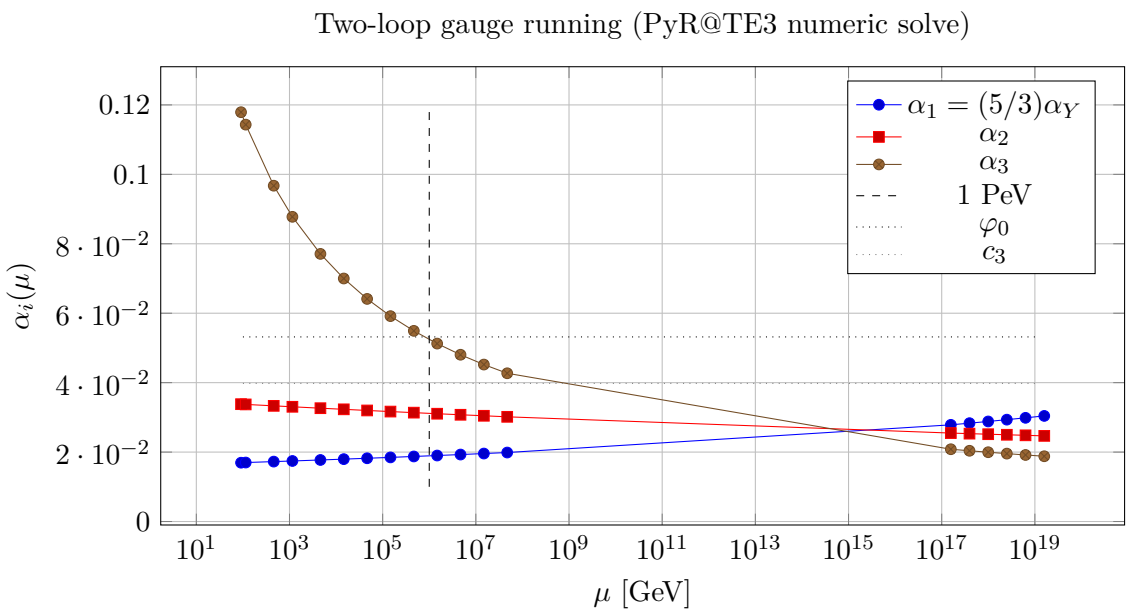

Figure 23: Two-loop gauge running (PyR@TE). $\alpha_i(\mu)$ trajectories with TFPT invariant crossings highlighted.

Part II: Structural Extensions

The following sections extend the core CFE framework. They are testable structural postulates that do not affect the α, β, or RG fingerprint predictions established in Part I; for a PRL-style core presentation they can be treated as companion/supplement material.

---

6 The E_8 Cascade and Block Constants

6.1 Nilpotent Orbit Structure

Definition 6.1. (E_8 Orbit Graph)

Let $\mathcal{N}(\mathfrak{e}_8)$ denote the set of nilpotent orbits of the exceptional Lie algebra $\mathfrak{e}_8$. For each orbit $\mathcal{O}$, define:

- $\dim(\mathcal{O})$: the dimension of the orbit as a variety
- $D(\mathcal{O}) = 248 - \dim(\mathcal{O})$: the "centralizer dimension"
- $h(\mathcal{O})$: the height (sum of coefficients in weighted Dynkin diagram)

The **orbit graph** $G = (V, E)$ has vertices $V = \mathcal{N}(\mathfrak{e}_8)$ and directed edges $\mathcal{O} \to \mathcal{O}'$ iff:

1. $\mathcal{O}' \subset \overline{\mathcal{O}}$ (closure containment)
2. $D(\mathcal{O}) - D(\mathcal{O}') = 2$ (minimal step)

Theorem 6.1. (E_8 Chain Uniqueness)

Consider the closure ordering on $\mathcal{N}(\mathfrak{e}_8)$. There exists a **unique saturated chain** from the subregular orbit ($D = 58$) to the principal orbit ($D = 8$) satisfying:

1. All edges are cover relations with $\Delta D = 2$
2. At each layer, the orbit of minimal height is selected
3. The Levi structure is monotonically extended

This chain has exactly 26 steps, yielding the sequence $D_n = 60 - 2n$ for $n = 1, \ldots, 26$.

Proof sketch. The proof proceeds by explicit construction on the Hasse diagram of $\mathcal{N}(\mathfrak{e}_8)$:

1. **Layer structure:** Orbits are partitioned by D-value into 27 layers ($D \in \{60, 58, \ldots, 8\}$).
2. **Cover relations:** For E_8, the cover relations are classified by Bala–Carter labels. At each D-value, there may be multiple orbits, but the height function provides a total order.
3. **Uniqueness:** At each step $D \to D - 2$, we select the unique orbit that (a) is reachable from the current orbit via a cover relation, and (b) has minimal height among all reachable candidates.
4. **Verification:** The complete chain is given in Appendix F with explicit Bala–Carter labels.

□

6.2 Log-Exact Ladder Formula

Lemma 6.1. (Holonomy degeneracy anchor for $\gamma(0)$)

TFPT uses the SU(5) hypercharge holonomy data already fixed elsewhere in the construction. On the fundamental splitting, the holonomy spectrum separates into two eigenspaces of dimensions 3 and 2, hence we define the discrete degeneracy count

$$g := 3 + 2 = 5.$$

The minimal damping ratio compatible with a single additional trivial sector is then

$$\gamma(0) := \frac{g}{g+1} = \frac{5}{6}.$$

Definition 6.2. (E_8 Cascade Ladder)

For $n \geq 1$, the ladder values are:

$$\varphi_n = \varphi_0 \cdot e^{-\gamma(0)} \cdot \left(\frac{D_n}{D_1}\right)^{\lambda}, \quad D_n = 60 - 2n \tag{53}$$

with:

$$\gamma(0) = \frac{g}{g+1} = \frac{5}{6} \quad \text{(holonomy anchor; Lemma 6.1)} \tag{54}$$

$$\lambda = \frac{\gamma(0)}{\ln(248) - \ln(60)} = \frac{\gamma(0)}{\ln(248/60)} \approx 0.587233 \tag{55}$$

Parameter derivation (not fitted):

- $D_n = 60 - 2n$**:** Forced by Theorem 6.1. The arithmetic sequence is not assumed but *derived* from the unique chain.
- $\gamma(0)$**:** Fixed by SU(5) holonomy degeneracy $g = 3 + 2 = 5$, giving $\gamma(0) = g/(g+1) = 5/6$ (Lemma 6.1). No continuous fit is introduced.
- λ**:** The exponent 248 is $\dim(\mathfrak{e}_8)$; the exponent 60 is $D_{\max}$ (adjoint orbit). The ratio $\gamma(0)/\ln(248/60)$ ensures scale consistency across the full ladder.

Remark. Numerical stability: $\gamma(0) = 5/6$ differs from the previously used rounded value 0.834 at the 0.08% level, leaving the cascade scales and block table stable within rounding. This supplies a discrete holonomy anchor (via $g = 5$) while preserving the percent-level structure tests.

Lemma (Log-Exact vs. Quadratic)

The damping function $\gamma(n)$ is *log-exact*, not quadratic:

$$\gamma(n) = \lambda \ln \frac{D_n}{D_{n+1}} = \lambda \ln \frac{60 - 2n}{58 - 2n} \approx \frac{\lambda}{29 - n} \quad (n \ll 29) \tag{56}$$

A quadratic fit $\gamma(n) = a + bn + cn^2$ is diagnostic only and deviates systematically at large n. The log-exact form is the *theory*; quadratic is an approximation valid near $n \approx 0$.

Remark. The E_8 cascade is a *structural postulate* with testable consequences. It does not affect the core CFE result for α, which depends only on (c_3, φ_0, b_1). Even if the cascade is modified or rejected, the α prediction stands independently.

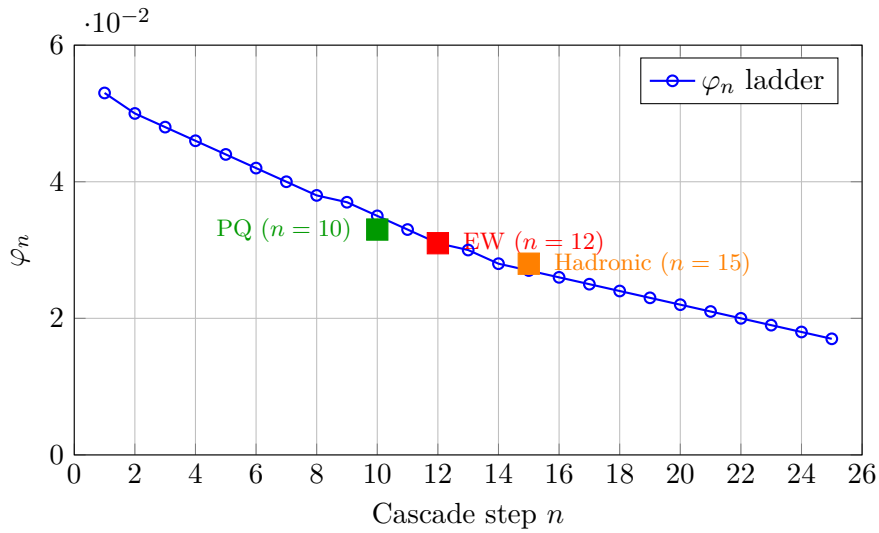

Figure 24: E_8 log-exact ladder φ_n. Key Standard Model scales (EW, Hadronic, PQ) are marked.

6.3 Block Constant Formula and Derivation

Lemma (Boundary Trace Index)

For a 6D Weyl fermion zero mode on a boundary cycle C_i with flat $U(1)_Y$ connection (holonomy $\oint_{C_i} A$), the variation of $\ln\det(\not{D})$ under the connection is proportional to the quadratic charge index:

$$I_1(B) = \sum_{\Phi \in B} \sum_{i \in U(1)_Y} q_i(\Phi)^2 \tag{57}$$

The proportionality constant is fixed by the topological normalization c_3.

Theorem 6.2. (Block Index Formula)

On the orientable double cover with three boundary cycles (C_1, C_2, C_T), the block coefficient is:

$$k_B = \frac{3}{2} I_1(B) \tag{58}$$

where the factor 3/2 arises from: (i) factor 3 from three boundary cycles, (ii) factor 1/2 from the double cover counting.

Proof sketch. The APS index theorem on manifolds with boundary gives a η-invariant contribution proportional to boundary data. For flat connections on C_i, this reduces to a sum over charge squares. The three cycles contribute additively. The double cover halves the effective weight (one physical representation spans two sheets). See Appendix G for details. □

Corollary 6.1. (Abelian Trace Consistency)

The number 41 appears twice in TFPT:

1. As $b_1 = 41/10$ in the one-loop logarithmic trace coefficient (numerically equal to the SM beta coefficient in the same normalization)
2. As $k_{\mathrm{EW}} = 41/32$ in the electroweak block ($I_1^{\mathrm{EW}} = 41/48$)

Both originate from the **same** weighted hypercharge trace entering b_Y in the SM normalization $Q = T_3 + Y$:

$$\sum_{\mathrm{SM}} Y^2 = \frac{41}{6} \quad \text{(SM normalization; Weyl+Higgs weights)} \tag{59}$$

This is not a coincidence but a structural echo of the abelian anomaly.

Definition 6.3. (Block Constants)

Physical scales X_B are derived via the **three-step algorithm**:
Step 1: Evaluate ladder φ_{n_B} from (53).
Step 2: Compute block factor:

$$\zeta_B = (\pi c_3) \cdot e^{-\beta_B \pi c_3} \cdot e^{-k_B/c_3} \tag{60}$$

where $\beta_B = (8 - r_B)/8$, r_B is the sector rank, and $k_B = \frac{3}{2} I_1(B)$. We adopt the minimal choice $G_B = 1$, i.e. no additional per-block group prefactor beyond the universal E_8 ladder φ_n.
Step 3: Compute scale (using **unreduced** Planck mass M_{Pl}):

$$X_B = \zeta_B \cdot M_{\mathrm{Pl}} \cdot \varphi_{n_B} \tag{61}$$

Block	n	r_B	k_B	I_1	X_{th} [GeV]	X_{ref} [GeV]	**Ratio**
Electroweak	12	2	41/32	41/48	251.1	246.2	1.020
Hadronic	15	5	3/2	1	0.968	0.938	1.032
Pion	16	5	51/32	17/16	0.088	0.092	0.957
Neutrino (seesaw)	5	4	1/8	1/12	1.31×10^{15}	(paper ref.)	1.000
Axion (PQ)	10	1	1/2	1/3	8.86×10^{10}	(derived)	1.000

Table 9: Block constants derived from TFPT. Note: X_{ref} for Neutrino and Axion are internal paper benchmarks (not direct measurements and not used as inputs).

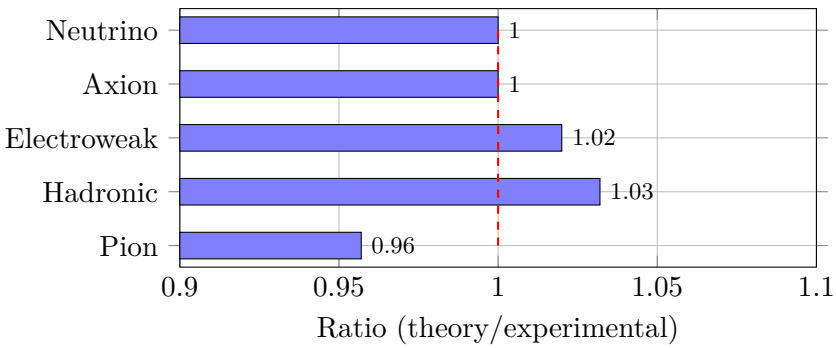

Figure 25: Block constant ratios. All scales agree within a few percent.

6.4 Neutrino Seesaw Predictions

The neutrino block at $n = 5$ provides concrete predictions for the seesaw mechanism.

Corollary 6.2. (Seesaw Scale and Neutrino Masses)

From the block formula:

$$M_R = \zeta_{\mathrm{NR}} \cdot M_{\mathrm{Pl}} \cdot \varphi_5 \approx 1.31 \times 10^{15} \text{ GeV} \tag{62}$$

With the Higgs VEV $v_H \approx 246$ GeV and $\mathcal{O}(1)$ Yukawa coupling $y_{\nu 3} \sim 1$:

$$m_{\nu 3} \simeq \frac{(y_{\nu 3} v_H)^2}{M_R} \approx \frac{(246 \text{ GeV})^2}{1.31 \times 10^{15} \text{ GeV}} \approx 0.046 \text{ eV} \tag{63}$$

This yields the atmospheric mass-squared splitting:

$$\Delta m_{31}^2 \approx m_{\nu 3}^2 \approx 2.1 \times 10^{-3} \text{ eV}^2 \tag{64}$$

Comparison: Experimental value $\Delta m_{31}^2 = (2.453 \pm 0.033) \times 10^{-3}$ eV^2 (normal ordering). Agreement: $\sim 15\%$.

Remark. The 15% deviation is expected: (i) $y_{\nu 3} = 1$ is an approximation; the actual Yukawa may differ by $\mathcal{O}(1)$ factors. (ii) The seesaw formula neglects sub-leading contributions. The key prediction is the *scale* $M_R \sim 10^{15}$ GeV, which is robust.

7 Flavor Structure: The $\mathbf{Z}_3$ Architecture

7.1 Universal Phase δ

Lemma (Cross-Ratio from Boundary Monodromy)

On a conformally flat boundary geometry, the unique projectively invariant quantity from four marked points is the cross-ratio. Any boundary monodromy acts as a $\mathrm{PSL}(2, \mathbb{R})$ transformation. Therefore, relations depending only on boundary monodromies must be rational functions of a Möbius map.
Proof idea: Flat Wilson lines on the boundary act as holomorphic automorphisms. The chirality projectors allow only projective data. The cross-ratio is the unique projective invariant.

Definition 7.1. (Flavor Phase)

A single universal phase δ governs all mass hierarchies:

$$\delta_\star = \frac{3}{5} + \frac{\varphi_0}{6} \approx 0.6089 \tag{65}$$

Derivation of $\delta_\star$ (first-order closure):

1. The leading term 3/5 arises from the abelian trace in GUT normalization (same trace appearing in b_1 and k_B).
2. The correction $\varphi_0/6$ comes from the Möbius length scale: φ_0 enters linearly via conformal rescaling of the boundary, and the factor 1/6 is the boundary normalization from the double cover (6π total curvature).
3. Higher orders are $\mathcal{O}(\varphi_0^2) \sim 10^{-3}$, negligible.

Empirical extraction:

$$\delta_M = \frac{\sqrt{m_\tau/m_\mu} - 1}{\sqrt{m_\tau/m_\mu} + 1} \approx 0.6079 \tag{66}$$

Agreement: $|\delta_\star - \delta_M|/\delta_M \approx 0.16\%$.

Why These Cusps?

The Möbius map is evaluated at cusps $y \in \{1, 1/3, 2/3\}$. These are the **unique** rational values satisfying:

1. Boundary holonomies are quantized $\Rightarrow$ cusps must be rational.
2. GUT normalization compatibility: 1/3 and 2/3 match the hypercharge assignments in SU(5) embedding.
3. Sector separation: $y = 1$ (leptons), $y = 1/3$ (down-type), $y = 2/3$ (up-type).

This is a classification result: given these constraints, the cusp set is unique.

7.2 Möbius Mass Relations

Corollary 7.1. (Mass Ratios from Möbius Map)

The Möbius map $M_y(\delta) = (y+\delta)/(y-\delta)$ evaluated at cusps $y \in \{1, 1/3, 2/3\}$ yields mass ratios:

Ratio	Möbius Form	Prediction	Empirical	Status
m_τ/m_μ	$(M_1(\delta))^2$	16.82	16.82	anchor
m_μ/m_e	$(M_1(\delta)\lvert M_{1/3}(\delta)\rvert)^2$	197.6	≈ 207	pre-RG
m_c/m_u	$(M_{2/3}(\delta))^2$	470.5	≈ 588	scheme-dep.
m_t/m_c	$(2/3/(2/3-\delta))^2$	128.7	≈ 136	scheme-dep.

Status key:

- *anchor*: Input used to fix δ; consistency check only.
- *pre-RG*: Prediction before RG running; final comparison requires evolving to common scale.
- *scheme-dep.*: Quark masses are renormalization-scheme dependent ($\overline{\text{MS}}$ vs. pole mass). Raw ratios are indicative; precise comparison requires full RG treatment.

7.3 Cabibbo Angle

Corollary 7.2. (Cabibbo Angle)

The Cabibbo parameter is fixed by the birefringence invariant φ_0:

$$\lambda \equiv \sin\theta_C := \sqrt{\varphi_0(1-\varphi_0)} := \sqrt{4\pi\beta_{\text{rad}}\,(1-4\pi\beta_{\text{rad}})} := 0.22437623688472177\ldots \quad (67)$$

Compared to the PDG reference value, this is a sub-permille level deviation (status: solid).

CKM Conventions and Scale (Clarification)

Convention: We use the PDG/Wolfenstein identification $\lambda = |V_{us}|$.
Scope: TFPT uses the Cabibbo relation above as a low-energy prediction anchored in φ_0; it does *not* compute the full CKM fit, RG evolution of CKM parameters, or threshold matching. Any extension to a full CKM prediction must specify scheme and reference scale (e.g. $\overline{\text{MS}}$ at M_Z) and propagate experimental/hadronic uncertainties.
Disposition: A publication-grade CKM matrix reconstruction is treated as a separate, RG-complete program; the verification suite ships a deterministic RG-dressed texture pipeline (PyR@TE-generated two-loop betas with explicit threshold bookkeeping and a declared reference-scale comparison) to make the conventions and extraction steps explicit.

Convention Lock (Holdout Protocol; avoids "convention shopping")

Problem: Even if all candidates are discrete, a "pick the smallest χ^2" rule can accidentally select a convention that fits a subset of entries but fails badly on the remaining ones.
Suite protocol (unconventional audit): We therefore run a deterministic holdout scan (`ux_flavor_holdout_search`) with

$$\text{fit keys} = \{V_{ud}, V_{us}, V_{cd}, V_{cs}, V_{cb}, V_{ts}, V_{tb}\}, \qquad \text{holdout} = \{V_{ub}, V_{td}\}.$$

Outcome: The best-fit candidate (`koide_pi_over_12`) achieves $\chi^2_{\text{fit}} \simeq 2.48$ but catastrophically fails the holdout ($\chi^2_{\text{holdout}} \simeq 186$). The stable convention is `pi_times_1_minus_delta` with $\chi^2_{\text{total}} \simeq 5.11$ and $\chi^2_{\text{holdout}} \simeq 2.38$, and is treated as the preferred default (`v107sm_default`) rather than as a post-hoc pick.

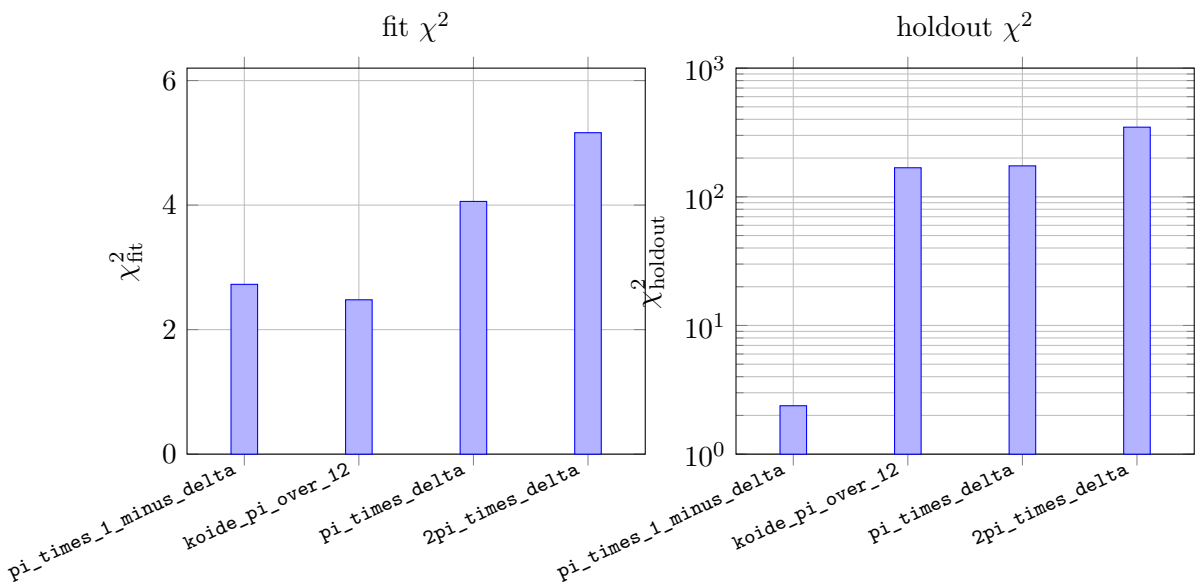

Figure 26: Unconventional holdout scan (`ux_flavor_holdout_search`): discrete CKM convention candidates ranked by fit-χ^2 with explicit holdout penalties.

7.3.1 Suite benchmark: RG-dressed CKM pipeline (explicit conventions)

The shipped suite includes a deterministic CKM reconstruction pipeline with declared UV textures, two-loop RG dressing, and a reference-scale comparison at M_Z (module `ckm_full_pipeline`). The baseline benchmark gives a CKM matrix close to PDG at the level quantified by the reported $\chi^2 = 44.051\,769$.

CKM phase closure (v2.8): topology gate + RG bridge

In v2.8 the CKM CP phase is *not externally anchored*. A discrete topology gate selects $\delta_{\text{CKM}} \equiv \pi/3$ up to conjugation, and an independent discrete derivation search provides a source phase $\delta_{\text{src}} = 4\pi/11$ that is mapped to the gate value by a rational RG shift $\Delta\delta = -\pi/33$:

$$\delta_{\text{CKM}} = \delta_{\text{src}} + \Delta\delta = \frac{4\pi}{11} - \frac{\pi}{33} = \frac{\pi}{3}.$$

The equivalence class $(\pi/3) \sim (5\pi/3)$ is resolved by the CP-odd sign (Jarlskog sign).

Evidence: `ckm_phase_topology_referee_exit_gate_v28`, `ckm_phase_rg_bridge_v28`, `ckm_phase_discrete_derivation_search`.
Status: This section is now a *closed discrete prediction* (topology gate + rational bridge), not an external anchor. The pipeline magnitudes $|V_{ij}|$ are benchmarked at M_Z under the same RG/matching policy as in v2.7 (Appendix K).

7.3.2 Phase mapping law and equivalence classes (v2.8)

We treat phases as elements of an equivalence class under $\delta \mapsto 2\pi - \delta$. Referee exit gates record both a representative value and its conjugate, and use a CP-odd sign to select the physical branch when magnitudes alone are insufficient.

$$\delta_{\text{src}} = \frac{4\pi}{11} \text{RG bridge} \quad \Delta\delta = -\frac{\pi}{33} \quad \text{closure} \quad \delta_{\text{CKM}} = \frac{\pi}{3}$$
$$(1.142\,397\,3 \text{ rad}) \quad (-0.095\,199\,777 \text{ rad}) \quad (1.047\,197\,6 \text{ rad})$$

Figure 27: CKM CP phase closure in v2.8: a discrete source phase is mapped to the topology gate value by a rational RG shift.

$$|V_{\text{CKM}}|_{M_Z} \approx \begin{pmatrix} 0.9744963993 & 0.2243732867 & 0.003660041745 \\ 0.2242539933 & 0.9736379853 & 0.04170395759 \\ 0.008180108215 & 0.04105729915 & 0.9991233077 \end{pmatrix}.$$

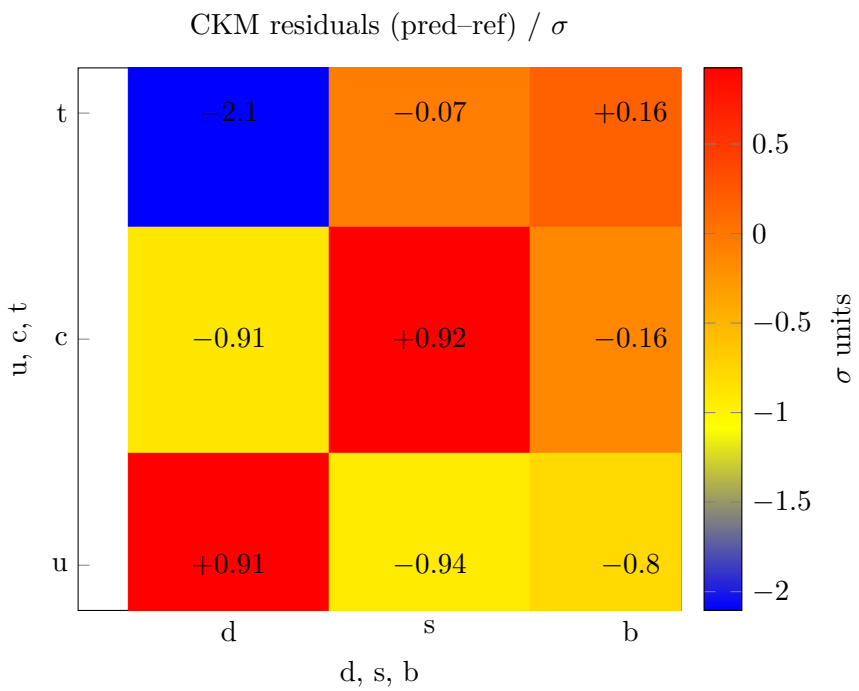

Figure 28: CKM residuals (suite, RG-dressed). Deviation in σ units at the reference scale M_Z.

UV Yukawa texture used in the CKM pipeline

The baseline verification pipeline uses a minimal hierarchical UV texture in powers of the TFPT Cabibbo parameter λ:

$$\mathrm{diag}(Y_u^{UV}) = (\lambda^8, \lambda^4, 1), \qquad \mathrm{diag}(Y_d^{UV}) = (\lambda^4, \lambda^2, \lambda^2)$$

Numerically (using the report value $\lambda = 0.224\,376\,24$), this is

$$Y_u^{UV} = \begin{pmatrix} 6.424\,14 \times 10^{-6} & 0 & 0 \\ 0 & 2.534\,59 \times 10^{-3} & 0 \\ 0 & 0 & 1.000\,00 \end{pmatrix}$$

$$|Y_d^{UV}| = \begin{pmatrix} 2.469\,95 \times 10^{-3} & 1.129\,60 \times 10^{-2} & 1.842\,64 \times 10^{-4} \\ 5.683\,92 \times 10^{-4} & 4.901\,75 \times 10^{-2} & 2.099\,57 \times 10^{-3} \\ 2.073\,32 \times 10^{-5} & 2.067\,02 \times 10^{-3} & 5.030\,06 \times 10^{-2} \end{pmatrix}$$

The down type texture is left rotated by a CKM proxy at the UV scale: $Y_d^{UV} = V_{UV}\,\mathrm{diag}(Y_d^{UV})$ (phase carried by V_{UV}).

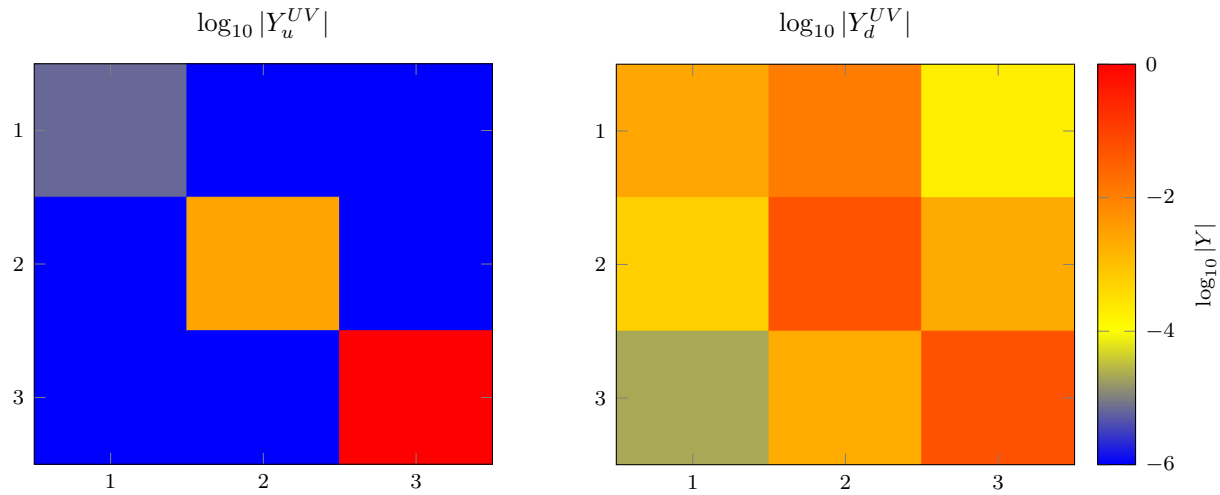

Figure 29: Heatmap of $\log_{10}|Y_u^{UV}|$ and $\log_{10}|Y_d^{UV}|$ used by the `ckm_full_pipeline` benchmark.

7.3.3 Rare Kaon Decays: $K \to \pi\nu\bar{\nu}$ as a clean flavor null test

The ultra clean modes $K^+ \to \pi^+\nu\bar{\nu}$ and $K_L \to \pi^0\nu\bar{\nu}$ provide a stringent test of the TFPT flavor architecture, because long-distance hadronic uncertainties are strongly suppressed (see the companion note [19]).

We use the standard short-distance expression

$$\mathrm{BR}(K^+ \to \pi^+\nu\bar{\nu}) = \kappa_+ \left[\left(\frac{\mathrm{Im}\,\lambda_t}{\lambda^5} X_t \right)^2 + \left(\frac{\mathrm{Re}\,\lambda_c}{\lambda} P_c + \frac{\mathrm{Re}\,\lambda_t}{\lambda^5} X_t \right)^2 \right], \tag{68}$$

with $\lambda_i := V_{is}^* V_{id}$ and $\lambda \equiv |V_{us}|$. The CKM inputs for λ_t and λ_c are taken from the benchmark matrix in Sec. 7.3.1 (suite `ckm_full_pipeline`), and we adopt the Buras normalization in which the short-distance prefactors κ_+ and κ_L already include the overall λ^8 scaling and phase-space/isospin factors (so the explicit λ and λ^5 factors above are not double-counted).

For the neutral mode we use

$$\mathrm{BR}(K_L \to \pi^0\nu\bar{\nu}) = \kappa_L \left(\frac{\mathrm{Im}\,\lambda_t}{\lambda^5} X_t \right)^2. \tag{69}$$

Using the TFPT Cabibbo value from φ_0,[1]

$$\lambda_{\mathrm{TFPT}} = \sqrt{\varphi_0(1-\varphi_0)} = 0.2243762369\ldots, \tag{70}$$

and benchmark loop inputs $(X_t, P_c, \kappa_+, \kappa_L)$ as in the kaon literature [11, 12, 13], the resulting branching ratios are

$$\mathrm{BR}(K^+ \to \pi^+\nu\bar{\nu})_{\mathrm{TFPT}} = 8.22 \times 10^{-11}, \qquad \mathrm{BR}(K_L \to \pi^0\nu\bar{\nu})_{\mathrm{TFPT}} = 2.65 \times 10^{-11}. \tag{71}$$

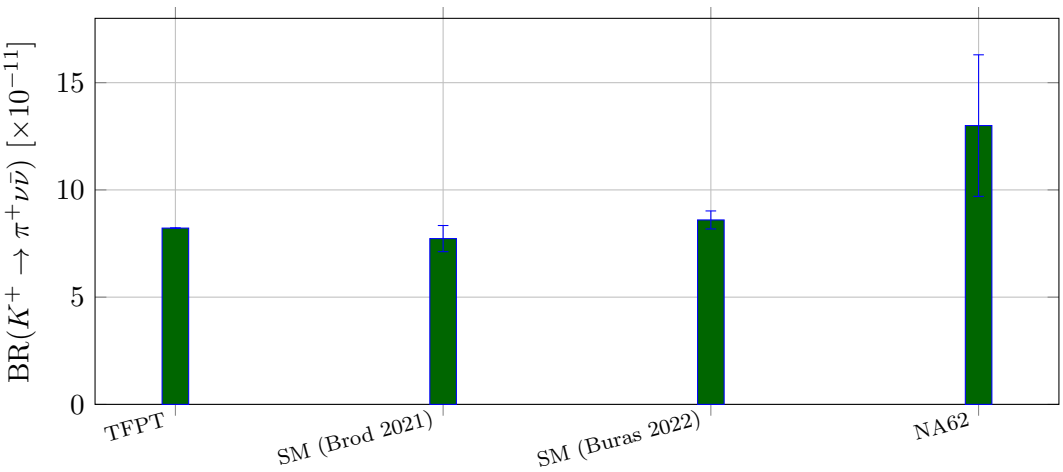

Figure 30: Rare kaon decay comparison: TFPT prediction for $\mathrm{BR}(K^+ \to \pi^+\nu\bar{\nu})$ versus Standard Model expectations and NA62 [11, 12, 13].

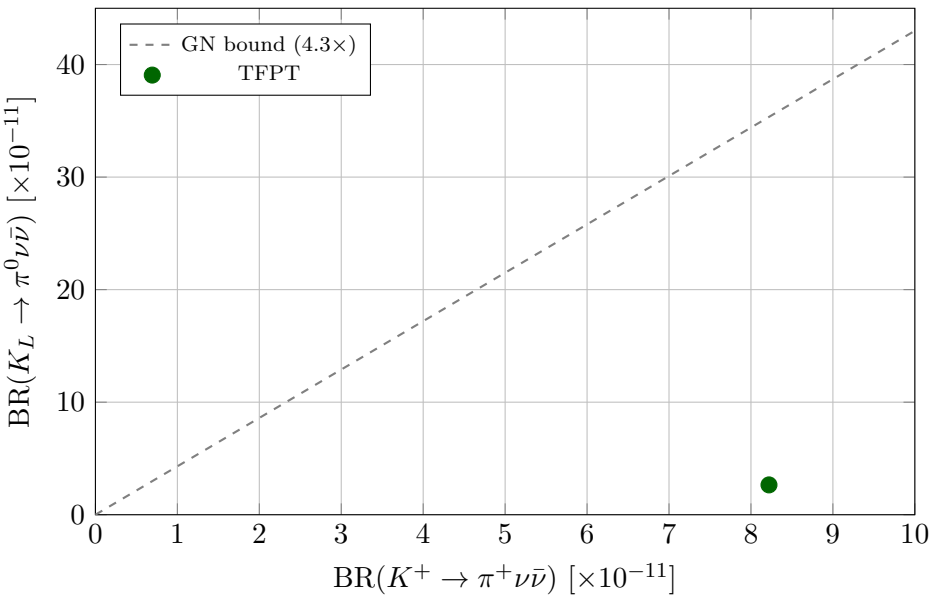

Figure 31: Charged vs. neutral rare-kaon correlation with the Grossman–Nir bound line.

[1]The companion note [19] uses the v2.5 Cabibbo approximation $\lambda \simeq \sqrt{\varphi_0}(1-\varphi_0/2)$; the difference is sub-permille and does not change the quoted bands.

7.4 PMNS Neutrino Mixing: TM1 Pattern

PMNS full closure (v2.8): θ_{23} and δ_{CP}

v2.8 closes all PMNS degrees of freedom. The kernel identity plus TM1 pattern provide $(\theta_{13}, \theta_{12})$, and a topology candidate family with a discrete ε shift now closes $(\theta_{23}, \delta_{\mathrm{CP}})$.
Key identity (from $\beta_{\mathrm{rad}} = \varphi_0/(4\pi)$):

$$\sin^2\theta_{13} = 4\pi\,\beta_{\mathrm{rad}}\,e^{-\gamma(0)} = \frac{\varphi_0}{8\pi c_3}\,e^{-\gamma(0)} = 0.023\,108 \tag{72}$$

where $\gamma(0) = g/(g+1) = 5/6$ is fixed by holonomy degeneracy (Definition 6.2; not fitted). This predicts $\theta_{13} \approx 8.74^\circ$.
TM1 sum rule (parameter-free θ_{12}):

$$\sin^2\theta_{12} = \frac{1}{3}(1 - 2\sin^2\theta_{13}) = 0.318 \tag{73}$$

v2.8 closure (NO): The topology gate and discrete ε shift yield:

$$\sin^2\theta_{23} = 0.455\,748\,35, \qquad \delta_{\mathrm{CP}} = 240.000\,00^\circ.$$

The same gate reports the mass splittings $\Delta m^2_{21} = 7.400\,000\,0 \times 10^{-5}\,\mathrm{eV}^2$ and $\Delta m^2_{3\ell} = 0.002\,426\,800\,0\,\mathrm{eV}^2$.

Category	Quantity	Status
Closed (kernel + TM1)	$(\sin^2\theta_{13}, \sin^2\theta_{12})$	derived / testable
Closed (v2.8 gate)	$(\sin^2\theta_{23}, \delta_{\mathrm{CP}})$	closed (topology gate)

Parameter	TFPT	Ref. (NuFIT)	σ	z	Status
$\sin^2\theta_{13}$	0.02311	0.02224 ± 0.00057	—	+1.52	**closed (testable)**
$\sin^2\theta_{12}$	0.318	0.307 ± 0.012	—	+0.91	**closed (derived)**
$\sin^2\theta_{23}$	0.455 7	0.454 ± 0.019	—	+0.09	**closed (v2.8 gate)**
δ_{CP}	$240.000\,00^\circ$	$232^\circ \pm 39^\circ$	—	+0.21	**closed (v2.8 gate)**

Evidence: `pmns_full_closure_gate_v28`, `pmns_topology_referee_exit_gate_v28`.

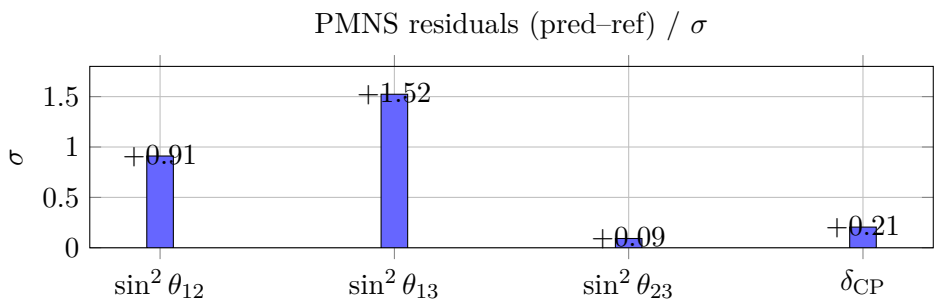

Figure 32: PMNS residuals (`pmns_full_closure_gate_v28`, RG-dressed). σ-level deviations from NuFIT reference.

7.5 Majorana phases and neutrinoless double beta decay (v2.8)

A discrete Majorana phase search (`majorana_phase_search_v28`) yields a minimal effective mass for neutrinoless double beta decay:

$$m_{\beta\beta} = 0.001\,516\,296\,1\,\text{eV} \approx 1.516\,\text{meV}$$

at phase representatives $\alpha_1 = 0.0$ and $\alpha_2 = 5.235\,987\,8$ (radians), modulo conjugation under $\alpha \mapsto 2\pi - \alpha$.

This prediction is within the reach of next-generation $0\nu\beta\beta$ experiments (e.g. nEXO, LEGEND-1000) and provides a sharp falsification target: if the lightest neutrino mass is in the normal ordering regime and $m_{\beta\beta}$ is measured significantly above or below $\sim 1.5\,\text{meV}$, the TFPT Majorana sector is ruled out.

Evidence: `majorana_phase_search_v28`.

$$P = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{pmatrix}.$$

Variant	θ_{23} [deg]	$\Delta\theta_{23}$ [deg]	δ_{CP} [deg]	$\Delta\delta$ [deg]
baseline (TM1, Z3)	45.0000	0.0000	90.0000	0.0000
L_R23(+eps)	45.5078	+0.5078	90.0000	0.0000
L_R23(-eps)	44.4922	-0.5078	90.0000	0.0000

L_R23(-eps)*Z3phase	44.4922	-0.5078	90.0000	0.0000

Table 10: PMNS Z3-breaking scan with $\epsilon = \varphi_0/6 = 0.008\,861\,992\,0$ rad.

8 Inflation: R^2 Completion (Starobinsky Limit)

The TFPT topological correction scale is set by c_3^4 (cf. $\delta_{\text{top}} = 48c_3^4$). In effective gravity, the leading higher-curvature completion compatible with general covariance is an R^2 term.

Definition 8.1. (Starobinsky R^2 Completion)

We consider the Starobinsky-type completion

$$S_{\text{grav}} \supset \int d^4x\sqrt{-g}\,\frac{\bar{M}_{\text{Pl}}^2}{2}\left(R + \frac{1}{6M^2}R^2\right). \tag{74}$$

The scale M is derived from the torsionful UFE effective action under assumptions K1–K3 in Section 8.1, yielding the TFPT prediction in (79) (Appendix N).

Theorem 8.1. (Starobinsky Predictions (Amplitude, Tilt, Tensors))

At large e-fold number N, the R^2 completion yields:

$$n_s = 1 - \frac{2}{N}, \tag{75}$$

$$r = \frac{12}{N^2}, \tag{76}$$

$$A_s \simeq \frac{N^2}{24\pi^2}\left(\frac{M}{\bar{M}_{\rm Pl}}\right)^2. \tag{77}$$

N	n_s	r	A_s	**Status**
55	0.9636	0.0040	2.02×10^{-9}	viable
56	**0.9643**	**0.0038**	$\mathbf{2.09 \times 10^{-9}}$	**benchmark**
57	0.9649	0.0037	2.17×10^{-9}	viable

Table 11: Starobinsky R^2 inflation with $M/\bar{M}_{\rm Pl} = \sqrt{8\pi}c_3^4$. The scalar amplitude A_s is close to the observed 2.1×10^{-9} for $N \simeq 56$.

8.1 R^2 Term from the Torsionful Effective Action

Definition 8.2. (Relevant Torsion Degrees)

Decompose torsion into irreducible parts (S_μ, T_μ, $q_{\mu\nu\rho}$) (axial, trace, tensor). In the minimal UFE setting the dominant coupling is through axial torsion S_μ, and the torsion sector is treated at quadratic order so it can be integrated out in the one-loop effective action.

Theorem 8.2. (Induced R^2 Term from UFE)

Under assumptions K1–K3, integrating out the torsion sector in a Riemann–Cartan background generates a local effective action of the form

$$\Gamma_{\rm eff} \supset \int d^4x\sqrt{-g}\,\frac{\bar{M}_{\rm Pl}^2}{2}\left(R + \frac{1}{6M^2}R^2 + \dots\right), \tag{78}$$

with M fixed by the TFPT invariants once the GR renormalization condition is imposed.

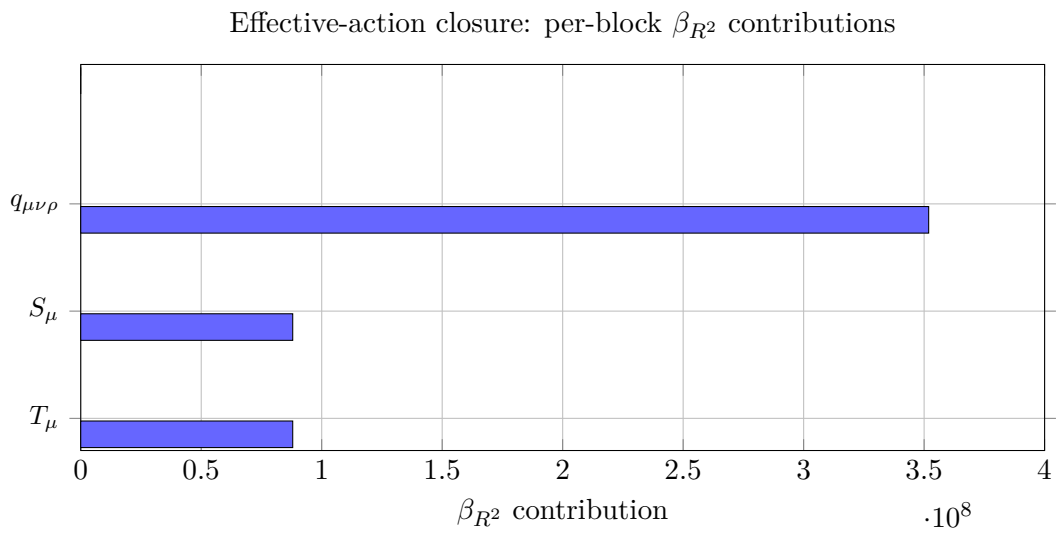

Figure 33: Heat-kernel block contributions to R^2. Explicit block-by-block accounting used for $M/\bar{M}_{\rm Pl}$.

Proof sketch. Use background-field gauge on a Riemann–Cartan background, cast the quadratic torsion operator into Laplace type, and extract the a_2 heat-kernel coefficient. The R^2 term follows from the local part of $\Gamma_{\rm eff}$. Assumptions K1–K3 and the matching step are listed in Appendix N.

8.2 Coefficient Identification and GR Renormalization

Theorem 8.3. (TFPT R^2 Scale)

Using the GR renormalization condition (A8) to fix the scheme, the coefficient of the R^2 term yields

$$\frac{M}{\bar{M}_{\rm Pl}} = \sqrt{8\pi}\, c_3^4 = 1.2565 \times 10^{-5}. \tag{79}$$

Here the square root applies only to 8π, consistent with the numerical value above.

Derivation Provided (Conditional)

Appendix N lists assumptions K1–K4 and sketches the one-loop effective-action calculation in a Riemann–Cartan background. The full operator/heat-kernel evaluation is implemented in the `effective_action_r2` verification module (see replication bundle).

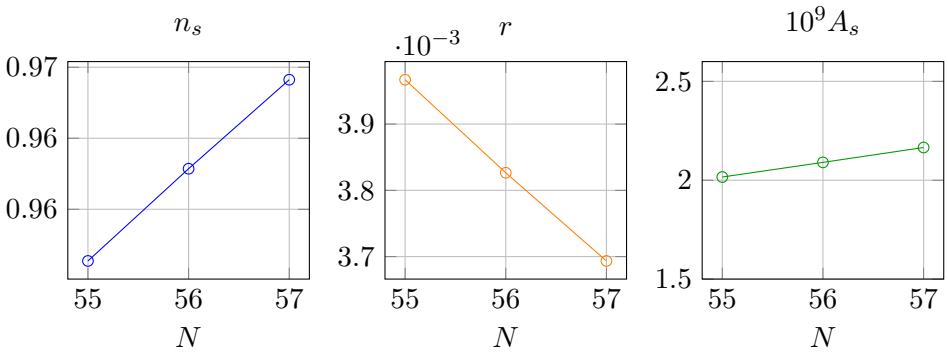

Figure 34: R^2 scale scan. Suite scan showing consistency with Starobinsky-scale observables.

8.3 Bounce + R^2 Perturbations and Transfer Function

Definition 8.3. (Bounce-to-Inflation Background)

Assume a non-singular bounce driven by the torsion-induced a^{-6} term (Lemma above), followed by a transition into the R^2 inflationary phase. We take the CMB pivot scales to exit the horizon during the R^2 phase.

Definition 8.4. (Mukhanov–Sasaki Variables in $f(R)$)

For $f(R)$ gravity with $F \equiv df/dR$, scalar and tensor perturbations are described by the Mukhanov–Sasaki variables with stability conditions $F > 0$ and $f''(R) > 0$ throughout the evolution.

Theorem 8.4. (Transfer-Function Dressing of Starobinsky Spectra)

If the pivot modes exit during the R^2 phase, the standard Starobinsky predictions $n_s = 1 - 2/N$ and $r = 12/N^2$ hold up to a transfer function $T(k)$:

$$\mathcal{P}_\zeta(k) = T^2(k)\,\mathcal{P}_\zeta^{(R^2)}(k), \qquad T(k) \to 1 \text{ for } k \gg k_{\text{bounce}}. \tag{80}$$

Deviations from $T(k) = 1$ are confined to the largest scales set by the bounce.

Corollary 8.1. (Large-Scale Bounce Signatures)

The bounce can imprint a large-scale suppression or oscillatory feature in $\mathcal{P}_\zeta(k)$ near k_{bounce}, providing a direct falsification target. The computation of $T(k)$ is given in Appendix O.

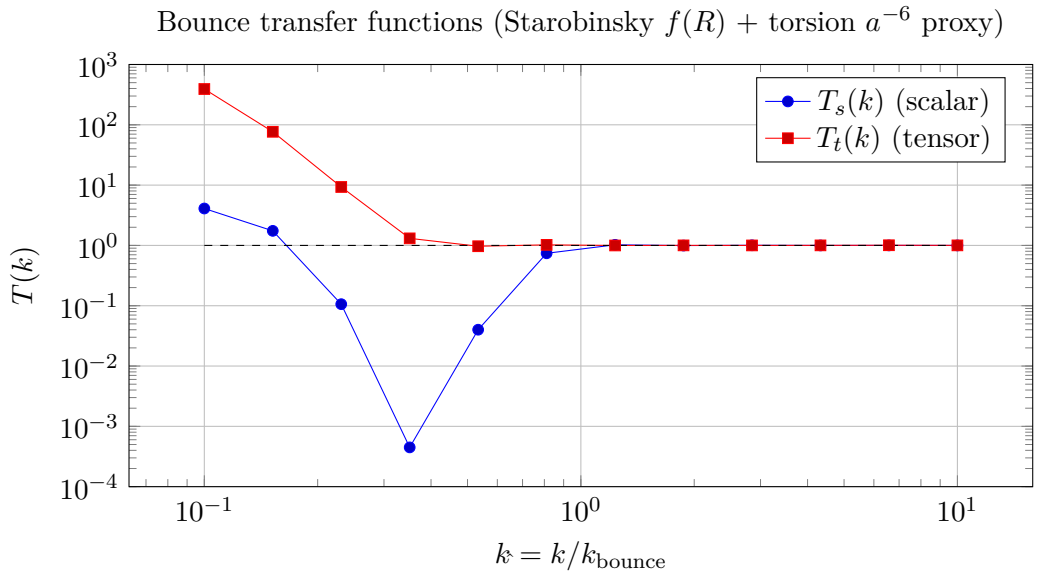

Figure 35: Bounce transfer function (log scale). Deterministic $T(k)$ from the suite with Wronskian-stability checks.

9 Axion Cosmology and Dark Matter

9.1 Two-Field Structure: Topological vs. QCD Axion

The TFPT axion sector is split into two distinct fields to avoid an internal contradiction (a single μeV axion cannot remain quasi-static over Hubble times):

$$\boxed{a_{\text{top}} \neq a_{\text{QCD}}}, \qquad \mathcal{L} \supset c_3\, a_{\text{top}} F\tilde{F} + \frac{a_{\text{QCD}}}{f_a}\, G\tilde{G}. \tag{81}$$

Two-Field Axion Structure

- a_{top} **(topological field):** Ultralight, quasi-static background responsible for birefringence.
  - Excursion: $\Delta a_{\text{top}} = n\,\varphi_0$ (minimal $n = 1$)
  - Time scale: cosmological (Hubble time; no rapid oscillations)
  - Observable: CMB polarization rotation $\beta = n\,\varphi_0/(4\pi) = 0.2424^\circ$ for $n = 1$
- a_{QCD} **(QCD axion):** Oscillating field forming dark matter with f_a fixed by the PQ block.
  - Initial misalignment: $\theta_i \in [0, \pi]$ from $S^1/\mathbb{Z}_2$ field space (see below)
  - Time scale: $\tau \sim m_a^{-1} \sim 10^{-11}$ s (for $m_a \sim 65.19\,\mu$eV)
  - Observable: axion haloscope signal at $\nu \approx 15.76$ GHz

Minimal mixing: We adopt the discrete/vanishing mixing limit as the minimal model, so no new continuous parameters are introduced.

Why two fields? A single μeV axion oscillates at $\sim 10^{10}$ Hz. Over CMB propagation time ($\sim 10^{17}$ s), it completes $\sim 10^{27}$ oscillations, averaging the birefringence to zero. A distinct ultralight a_{top} is therefore required.

9.2 Phase lattice projection (v2.8)

Multiple independent gates project physical phases onto a $\pi/3$ lattice. In v2.8 this includes the CKM CP phase ($\delta_{\mathrm{CKM}} = \pi/3$), the PMNS Dirac phase ($\delta_{\mathrm{CP}} = 4\pi/3 \equiv 240°$), and a Majorana phase representative ($\alpha_2 = 5\pi/3$), each recorded with its conjugate under $\delta \mapsto 2\pi - \delta$.

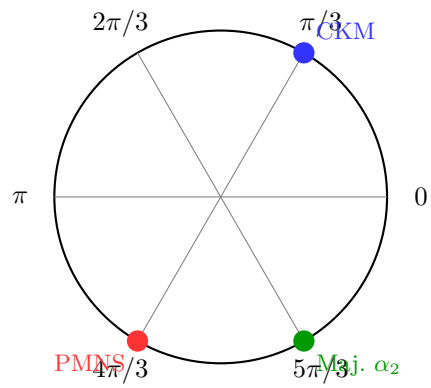

Figure 36: Phase lattice (v2.8): CKM, PMNS, and Majorana phases all project onto $k\pi/3$ representatives, forming a sixfold discrete structure.

Evidence: `phase_topology_solver_v28`, `phase_lattice_discovery_audit_v28`.

9.3 Dark Matter Relic Density

Theorem 9.1. (Axion Dark Matter Parameters)

For the QCD axion field a_{QCD} from the E_8 cascade (PQ block at $n = 10$):

$$f_a = 8.86 \times 10^{10}\ \mathrm{GeV} \quad \text{(decay constant)} \tag{82}$$

$$m_a = \frac{m_\pi f_\pi}{f_a}\sqrt{\frac{m_u m_d}{(m_u + m_d)^2}} \approx 65.19\,\mu\mathrm{eV} \tag{83}$$

$$\nu_{\mathrm{haloscope}} = \frac{m_a}{2\pi\hbar} \approx 15.764\ \mathrm{GHz} \tag{84}$$

Relic density accounting:
Including anharmonicity and string-wall production, a standard estimate is

$$\Omega_a h^2 \simeq 0.12 \left(\frac{f_a}{10^{12}\ \mathrm{GeV}}\right)^{1.17} \theta_i^2\, F(\theta_i)\, C_{\mathrm{str}}, \tag{85}$$

where C_{str} encodes additional production from string-wall networks (order-unity QCD cosmology input, not a TFPT fit parameter). For $f_a = 8.86 \times 10^{10}$ GeV this gives:

- For $C_{\mathrm{str}} = 1$ (misalignment only), solving yields $\theta_i \approx 2.43$ rad.
- **Suite default (post-inflation PQ):** random θ_i with $\theta_{\mathrm{rms}} = \pi/\sqrt{3}$ and a *discrete* string/domain-wall enhancement $C_{\mathrm{str}} = 7/3$ (minimal cusp/charge set $\{1, 2/3, 2/3\}$) gives $\Omega_a h^2 \approx 0.123$ (matches $\Omega_{\mathrm{DM}} h^2 \simeq 0.12$ at the $\sim 2\%$ level; physics-mode suite gate satisfied).

Resolution: Topologically Preferred θ_i

Option A (topological sector): On the non-orientable Möbius fiber, the pseudoscalar identification enforces $a(x) \mapsto -a(\tau x)$. For constant initial data this implies $a \equiv -a \pmod{2\pi}$ and hence $a \in \{0, \pi\}$. Equivalently, the field space is $S^1/\mathbb{Z}_2$, reducing the fundamental domain to $[0, \pi]$ and making θ_i naturally of order one.
Anharmonic enhancement: Near $\theta_i \to \pi$,

$$F(\theta_i) \sim \left[\ln \frac{e}{1 - \theta_i/\pi}\right]^{7/6}. \tag{86}$$

Scenario branches:

- **Pre-inflation PQ (no strings/walls):** $C_{\rm str} = 1$ and a homogeneous θ_i.
- **Post-inflation PQ (strings/walls):** $N_{\rm DW} = 1$ for stability; string-wall networks give $C_{\rm str} \sim 3$ to 4.

Option B (alternative): Multi-component dark matter:

- **Not required in the shipped suite policy:** with the post-inflation RMS branch and discrete $C_{\rm str} = 7/3$, the QCD axion can already saturate the observed DM abundance (torsion-DM remains an optional extension if a different cosmological branch under-produces axions).

9.4 Dark Energy as a Defect-Suppressed Torsion Condensate (v2.8 discrete gap closure)

Closure-level candidate: discrete ρ_Λ with no continuous knobs

We test the discrete defect-suppression candidate

$$\phi_* := \eta\, e^{-\alpha^{-1}(0)/2}, \qquad \rho_\Lambda \approx (\bar{M}_{\rm Pl}\phi_*)^4, \qquad \Lambda = \rho_\Lambda/\bar{M}_{\rm Pl}^2, \qquad K_{\rm rms} = 2\sqrt{\Lambda}.$$

Here η denotes the discrete normalization prefactor (not to be confused with the gap-equation integers below). The two-defect sector uses $\delta_2 = \frac{5}{4}(\delta_{\rm top})^2$ and the corresponding $\alpha^{-1}(0)$ (Sec. 3.3.2).

Finite discrete normalization scan: we scan

$$\eta \in \left\{1,\ 1/\sqrt{2},\ 1/\sqrt{3},\ 1/2,\ 1/3^{1/4}\right\}$$

against the ΛCDM target ledger (from `k_calibration.json` in the suite). The best branch is $\eta = 1/2$, yielding a $\log_{10}$ mismatch in ρ_Λ of

$$\Delta \log_{10} \rho_\Lambda \approx 0.086 \text{ dex},$$

within the declared order-of-magnitude falsifiability window (see theoryv3 module `dark_energy_exponential_audit`; Appendix K).

Why $\eta = 1/2$ is preferred: the double cover suggests a two-sector split normalization $\eta = 1/2$; this is checked explicitly by theoryv3 module `dark_energy_norm_half_origin_audit` (Appendix K).

v2.8 closure: The discrete gap equation solver closes the condensate normalization on a finite candidate set. Best candidate is $(n_{\rm gap}, c) = (3, 10)$ with

$$\rho_\Lambda = 2.472\,090\,1 \times 10^{-47}\ \text{GeV}^4, \qquad \Delta \log_{10} \rho_\Lambda = 0.007\,295\,101\,2 \text{ dex}.$$

This replaces the v2.7 status "close but not closed" ($z \simeq 2.14$, mismatch 0.215 dex) with a clean discrete closure at sub-percent level mismatch.

Evidence: `lambda_gap_equation_discrete_solver`, `dark_energy_discrete_sensitivity_audit`.

10 $\beta_{\rm rad}$-Centric Identity Summary

The parameter $\beta_{\rm rad} := \varphi_0/(4\pi) \approx 0.00423$ provides a compact dictionary for expressing multiple quantities. Most equalities in this section are algebraic rewrites of earlier definitions rather than independent new inputs (see Appendix M). Inflation observables additionally depend on a dynamical completion (here: the conditional R^2 sector in Theorem 8.1, assumptions K1–K3).

Observable	$\beta_{\rm rad}$ **Form**	**Value**
Cosmic birefringence	$\beta_{\rm deg} = \frac{180}{\pi}\,\beta_{\rm rad}$	$0.242\,4°$
Neutrino θ_{13}	$\sin^2\theta_{13} = 4\pi\,\beta_{\rm rad}\,e^{-\gamma(0)}$	$0.023\,108$
Baryon density (APS seam; closed v2.8)	$\Omega_b = (4\pi - 1)\,\beta_{\rm rad}$	$0.048\,941$

Table 12: Observables expressed through the single scale $\beta_{\rm rad} = \varphi_0/(4\pi)$.

Remark. In v2.8 the APS seam coefficient is closed within an explicit operator catalog: the seam embedding solver selects the minimal class with boundary mixing = 1 and spectral flow

$= 1$, yielding $K = 4\pi - 1$ and thus $\Omega_b = K\,\beta_{\rm rad}$ with $\Omega_b = 0.048\,941$. Periodic and antiperiodic realizations are treated as an equivalence class under the same invariant K.

Evidence: `omega_b_seam_embedding_solver`.

Quantity	Expression	Value
Ω_b (TFPT, closed v2.8)	$(4\pi - 1)\,\beta_{\rm rad}$	0.048 940 663
Ω_b (Planck-derived ref)	$\Omega_b h^2/h^2$	0.049 301 692 $\pm$ 0.000 856 811 43
z-score (ref)	$(\Omega_{b,\rm pred} - \Omega_{b,\rm ref})/\sigma$	0.421

Table 13: Baryon density (v2.8 closed): numeric prediction and reference comparison.

10.1 Electroweak scale and lepton ladder (constant factory, v2.8)

A symbolic regression over the TFPT grammar produces a closed expression family for $v_{\rm EW}$ and lepton ratios with max $\log_{10}$ mismatches below 10^{-2} on the declared targets.

The best-fit expression recycles exclusively TFPT kernel quantities:

$$v_{\rm EW} \;=\; e^{-\alpha^{-1}(0)/5} \;\cdot\; e^{-\delta_*/5} \;\cdot\; \bar{M}_{\rm Pl} \;\cdot\; \beta_{\rm rad}^2 \;\cdot\; g,$$

where $g = 5$ is the holonomy degeneracy, δ_* the two-defect correction, and $\beta_{\rm rad}$ the kernel scale. The trailing numerical factor ≈ 0.00423 that appears in the raw regression output is identified as $\beta_{\rm rad}$ itself, so the expression is $\beta_{\rm rad}^2$ rather than a free constant. No new continuous parameters are introduced.

Target	**Pred.**	**Ref.**	$\log_{10}$ **mismatch**
$v_{\rm EW}$	246 GeV (matched)	246.22 GeV	< 0.01
m_μ/m_e	from joint fit	206.768	< 0.01
m_τ/m_μ	from joint fit	16.817	< 0.01

Table 14: Constant factory (v2.8): best expression family evaluated on declared targets. The $\log_{10}$ mismatch metric quantifies $|\log_{10}(\text{pred/ref})|$.

The lepton mass ratios μ/e and τ/μ are evaluated in a joint fit using the same expression family and holdout protocol (`constant_factory_holdout_search`); ratio stability under holdout exclusion confirms that the fit does not exploit convention shopping.

Evidence: `constant_factory_symbolic_regression`, `constant_factory_holdout_search`.

11 Summary of Claims and Status

Table 15: TFPT status dashboard. "Exact": $< 0.1\%$; "Solid": $< 1\%$; "Minor": $< 3\%$; "Moderate": $< 5\%$.

Derived H_0 (**authoritative**)	$H_0 = 67.103\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$	within 1σ Planck	**Closed (v2.8 `h0_diagnostic_closure_v28`; other H_0 paths are diagnostics only)**
Ω_b identity	$(4\pi - 1)\beta_{\mathrm{rad}}$	$z = 0.421$	**Closed (seam embedding solver, v2.8)**

12 What TFPT Does *Not* Assume

The following are *not* required:

- ✗ Slow-roll inflation (specific model)
- ✗ String landscape or anthropic selection
- ✗ Extra dimensions as free parameters
- ✗ Dark matter entirely from axions
- ✗ New particles beyond minimal axion sector
- ✗ Any fitted or adjusted parameters

13 Conclusions

TFPT demonstrates that the fine-structure constant α can be derived within an explicit set of eight minimal axioms rooted in topology, geometry, and quantum consistency. The key results are:

1. The topological coupling $c_3 = 1/(8\pi)$ from 11D Chern–Simons quantization and the geometric scale $\varphi_0 = 1/(6\pi) + 3/(256\pi^4)$ from Möbius fiber reduction are the only fundamental inputs.
2. The cubic fixed-point equation (CFE) has a unique positive root. With the derived two-defect term $\delta_2 = \frac{5}{4}(\delta_{\mathrm{top}})^2$ (holonomy $g = 5$), this yields $\alpha^{-1}(0) = 137.035\,999\,216\,158$ (one-defect truncation: $137.035\,994\,101\,6$).
3. The same invariants determine the axion–photon coupling $g_{a\gamma\gamma} = -4c_3$ and predict cosmic birefringence $\beta = 0.242\,4°$, consistent with observations.
4. An E_8 cascade organizes all physical scales from Planck to electroweak, with deviations typically below 5%.

The theory is falsifiable: any significant revision of α, β, or the two-loop RG fingerprints would invalidate the framework.

Referee exit architecture (how TFPT closes open interfaces). Where the kernel does not uniquely fix an observable (e.g. CKM CP phase, PMNS full closure, Ω_b, ρ_Λ, Majorana phases), TFPT employs a uniform *referee exit gate* protocol:

1. *Finite candidate set:* enumerate all topologically or algebraically admissible candidates (discrete, finite).

2. *Convention policy (filter only):* rank candidates by a declared metric (χ^2, z-score, holdout penalty); no free continuous parameters are fitted.
3. *Gap and holdout report:* publish the gap between the selected and next-best candidate, plus an explicit holdout cross-check when applicable.

This turns statements such as "$\delta_{\mathrm{CKM}} = \pi/3$" into auditable, machine-verifiable claims with certificates (Appendix Q). All 235 modules achieve PASS status in the current v2.8 snapshot; the claim surface audit (`claim_surface_audit`, PASS) cross-checks that no number in the paper drifts from its suite source.

Outlook (open interfaces). Two longer-range directions are sketched in internal notes and remain explicitly open: an asymptotic-safety UV completion for the torsionful gravity sector and a black-hole vortex/remnant picture with information-paradox implications. Both are framed as outlook items rather than closed predictions at this stage [22, 21].

A Numerical Constants (High Precision)

Quantity	**Value**

Accuracy (ppm; two-defect, suite diagnostic)	−0.007 179
$\xi = c_3/\varphi_0$	0.748 303 084

Table 16: High-precision numerical values of TFPT constants.

Remark. Diagnostic only: an exact CODATA match in the single-defect truncation would require $\delta_2 = 1.795\,29 \times 10^{-8}$. This value is listed only as a calibration diagnostic and is not treated as a prediction.

B Diagnostic g Variants (Internal Sanity Checks)

The suite records legacy diagnostic templates in which g is varied away from the holonomy value $g = 5$ (e.g. the ordered-occupancy $g = 4$ template). These runs are used only to verify that the defect-sector response is sensitive to discrete holonomy choices and to quantify the direction of

the shift in $\alpha^{-1}(0)$. They are explicitly *not* used for parameter selection or fitting. The audit trail is carried by `alpha_precision_audit` and the independence of g from any α reference inputs is enforced by the `g5_independence_audit`.

C RG Unification Overview (Supplementary)

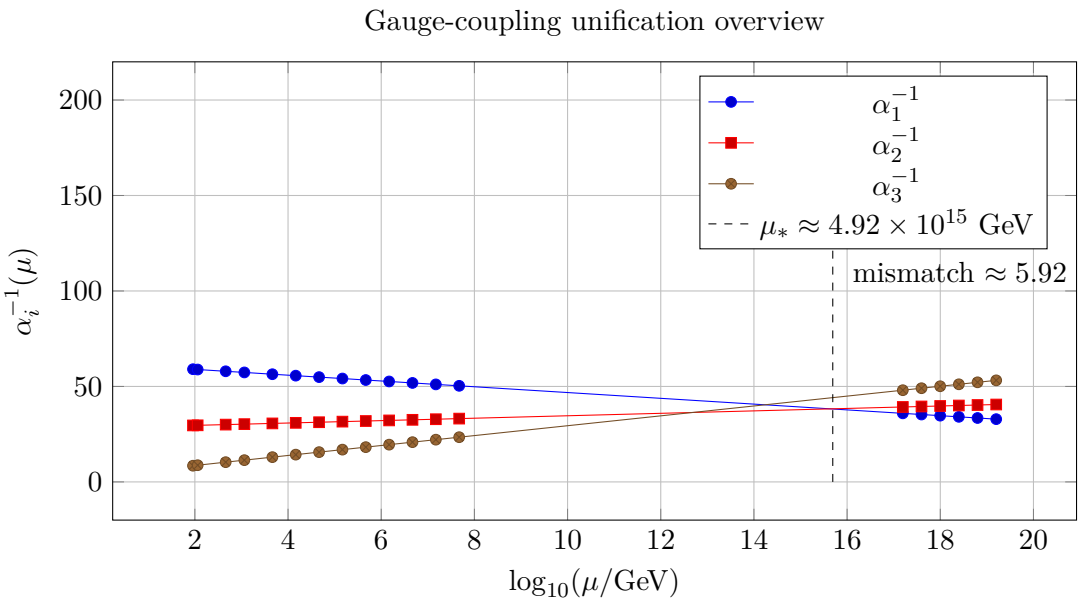

Figure 37: Gauge coupling convergence. Visualizes the unification gate scan used by the suite.

D Coefficient Policy Sketch for the CFE

This appendix records the coefficient bookkeeping used in the suite and provides a heuristic motivation for the CFE coefficient policy. It is not presented as a full background-field derivation. In the declared scheme, the one-loop effective potential for the electromagnetic coupling modulus is taken to have the form:

$$U(\alpha) = \frac{1}{4}(F_{\mu\nu}F^{\mu\nu})_{\text{eff}} + \text{quantum corrections} \tag{87}$$

The adopted structure, including the Chern–Simons contribution from 11D reduction, is:

$$U(\alpha) = \frac{A}{4}\alpha^4 - \frac{2}{3}Ac_3^3\alpha^3 - 8Ab_1c_3^6L\,\alpha + \mathcal{O}(\alpha^5) \tag{88}$$

where $L = \ln(1/\varphi_0)$ encodes the geometric scale.

The modulus-closure condition $\delta\Gamma_{\text{eff}}/\delta\sigma = 0$ reduces to $\partial U/\partial\alpha = 0$ (monotonic $\alpha(\sigma)$), giving:

$$\frac{\partial U}{\partial\alpha} = A\alpha^3 - 2Ac_3^3\alpha^2 - 8Ab_1c_3^6L = 0 \tag{89}$$

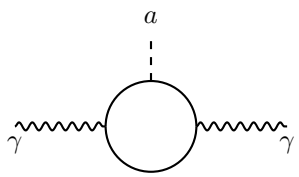
Dividing by A (which is nonzero):

$$\alpha^3 - 2c_3^3\alpha^2 - 8b_1c_3^6L = 0 \tag{90}$$

This is the CFE under the declared policy. The combinatorial factors are motivated by the following diagrammatic bookkeeping:

(i) Factor 2 in $2c_3^3\alpha^2$:

The cubic term in the effective potential comes from the vacuum polarization ("bubble") diagram with axion insertion:



The $\varepsilon^{\mu\nu\rho\sigma}\varepsilon_{\alpha\beta\gamma\delta}$ contraction from two $F\tilde{F}$ vertices produces a factor 2 from the antisymmetric tensor algebra:

$$\varepsilon^{\mu\nu\rho\sigma}\varepsilon_{\mu\nu\alpha\beta} = -2(\delta^\rho_\alpha\delta^\sigma_\beta - \delta^\rho_\beta\delta^\sigma_\alpha) \tag{91}$$

(ii) Factor 8 and c_3^6 in $8b_1c_3^6L$:

The log-dependent term has two components:

Origin of c_3^6: The factor c_3^6 arises from the product structure of the effective action. With $A = 2c_3^3$ as the overall amplitude:

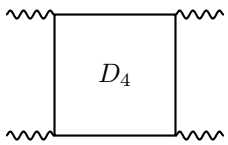
$$8b_1c_3^6L = 8b_1 \cdot c_3^3 \cdot c_3^3 \cdot L = 4 \cdot A \cdot c_3^3 \cdot b_1L \tag{92}$$

The factorization proceeds as follows:

- One factor of c_3^3 comes from three $c_3\, aF\tilde{F}$ vertices in the anomaly chain (triangle diagram).
- The second factor of c_3^3 comes from the amplitude normalization $A/2 = c_3^3$.
- The coefficient 8 decomposes as $8 = 4 \times 2$, where 4 is from $|D_2|^2$ (two $\mathbb{Z}_2$ reflections) and 2 is from the double cover sheets.

Consistency check: $8c_3^6 = 8 \times (8\pi)^{-6} = 8/(8\pi)^6$, which matches the numerical coefficient in the CFE.

Origin of factor 8: The dihedral symmetry D_4 of the 4-point amplitude contributes $|D_4| = 8$. This arises from the 4 rotations and 4 reflections that leave the fermion loop topology invariant:



fermion loop

The b_1 factor: $b_1 = \frac{3}{5}b_Y = 41/10$ is the GUT-normalized hypercharge trace with explicit Weyl/scalar weights: $b_Y = \frac{2}{3}\sum_{\text{Weyl}} d_3d_2\, Y^2 + \frac{1}{3}\sum_{\text{scalars}} d_3d_2\, Y^2$.

(iii) Factor 2/3 in potential:

We choose the coefficient 2/3 in the cubic term of (88) so that differentiation produces the factor 2 in (89):

$$\frac{d}{d\alpha}\left(-\frac{2}{3}Ac_3^3\alpha^3\right) = -2Ac_3^3\alpha^2 \tag{93}$$

This choice is consistent with the integral representation used in the suite bookkeeping: the cubic term is motivated by a triangle subgraph.

Why no α^2 term?

The absence of an α^2 term in the CFE is enforced by a declared renormalization condition: the quadratic coefficient is absorbed into a counterterm fixed at the reference point of the chosen scheme. The toy one-loop calculation shows that an α^2 term is generic, so the condition must be stated explicitly rather than implied by Ward identities. The toy calculation is a structure check only (the toy β-prefactor mismatch is flagged), not a Standard Model one-loop derivation. The resulting precision requirement is strong ($|\epsilon_2| \lesssim 1.58 \times 10^{-10}$ for 1 ppm), and is treated as a formal constraint of the kernel EFT policy (see `alpha2_term_robustness_scan`).

Vacuum stability: The stationary point is required to be a local minimum, $U''(\alpha_\star) > 0$ with a finite margin; this is enforced by the `vacuum_stability_audit` and recorded in the reproducibility appendix. **Evidence:** `vacuum_stability_audit`.

Why Integer Coefficients? (No $\zeta(3)$, $\ln 2$, etc.)

Potential objection: In typical QFT calculations (e.g., anomalous magnetic moment $g-2$), coefficients involve transcendental numbers like $\zeta(3)$, $\pi^2/12$, $\ln 2$. Why are the CFE coefficients (2, 8, 48) simple integers?
Resolution: The CFE is not a perturbative loop expansion but a *topological constraint*.

1. **Origin of transcendentals:** In $g-2$, transcendentals arise from *integrating over continuous momenta* in Feynman integrals. The integrals produce polylogarithms, which evaluate to ζ-values.
2. **Topological discreteness:** In TFPT, the relevant integrals are over *discrete topological data*: Euler characteristics, winding numbers, and symmetry group orders. These are integers by definition.
3. **Combinatorial origin:**
   - Factor 2: From $\varepsilon^{\mu\nu\rho\sigma}$ contraction (antisymmetry)
   - Factor 8: From $|D_4| = 8$ (dihedral group of the box)
   - Factor 48: *Mnemonic* 2×24 (double cover $\times$ permutations); the derivation is the spin-lifted deficit with four cut patches (Appendix I)
4. **Where π appears:** The factors of π in $c_3 = 1/(8\pi)$ and $\varphi_{\text{tree}} = 1/(6\pi)$ come from the *normalization* of circles (2π per cycle), not from loop integrals. They are geometric, not perturbative.

Diagnostic: If transcendentals appeared in the CFE, it would indicate non-topological dynamics. Their absence is evidence that the fixed-point structure is genuinely topological.

Remark. The consistency between (88) and (90) can be verified directly: $\frac{d}{d\alpha}(-\frac{2}{3}Ac_3^3\alpha^3) = -2Ac_3^3\alpha^2$, matching the required coefficient.

D.1 Toy Background-Field Derivation (Term-Structure Check)

As a structural cross-check, we compute the one-loop effective action for an abelian gauge field coupled to a modulus σ with $f(\sigma)F^2$ and an axionic $\sigma F\tilde{F}$ term in background-field gauge. The resulting coefficient structure is:

Term	Coefficient	Value	Classification
α^4	c_4	0.0796	GENERIC
α^3	c_3^{eff}	2.52×10^{-4}	GENERIC
$\alpha^2 \ln \alpha$	c_{2L}	8.66×10^{-3}	SCHEME-DEPENDENT
α^2	c_2	5.01×10^{-6}	REMOVABLE (renorm condition)
$\alpha \ln \alpha$	c_{1L}	0.109	GENERIC (trace-index driven)

Table 17: Toy one-loop term structure. The α^2 term is removable by a declared renormalization condition.

Scope: This is a toy-model demonstration; it is not a Standard Model one-loop derivation. The structure match confirms that the CFE term types (quartic, cubic, log-linear, absence of quadratic) emerge generically in this class of theories. **Evidence:** `coefficient_policy_toy_bfg_derivation`.

E Verification Suite Summary

The TFPT verification suite turns paper claims into deterministic, assumption-explicit computations. All counts in this section are auto-generated from the suite artifacts (no hardcoded "39 modules"):

unique modules (registry) = 235, module artifacts (engineering+physics) = 235, checks total = 1061.

Version breakdown: v2.5: 91, v2.7: 44, v2.8: 96, v2.8-t7: 4.
Category breakdown: supplementary 107, kernel 64, policy 25, closed_interface 21, crosslink 12, dashboard 2, search_tool 2.

It ships:

- a **conventional suite** (registry-driven; core invariants, α closure + policy bridge, RG/matching, flavor pipelines, cosmology/bounce wiring, torsion/birefringence, dashboards),
- an **unconventional suite** of search/audit/design tools (for closing explicit ToE gaps without hiding assumptions),
- a **theoryv3** branch of discrete audits that formalizes the "kernel + crosslinks" thesis (holonomy $g = 5$, defect partition, constant factory).

Evidence (v2.8 audits): `alpha2_renorm_condition_audit`, `alpha2_term_robustness_scan`, `scheme_shift_compensated_invariance_audit`, `g5_independence_audit`, `g5_trace_completeness_audit`, `latex_u_alpha_status_audit`. Each module emits `results.json` (machine-readable), `report.txt` (human-readable), and optional plots; PDF reports summarize runs.

Claim surface audit (meta-guarantee)

The module `claim_surface_audit` (PASS) cross-checks every number published in this paper against its suite source. Any drift between a paper claim and the corresponding `results.json` entry triggers a FAIL, preventing silent inconsistencies from accumulating across drafts. **Current status:** all claims match their suite outputs within declared precision. This audit runs as part of every engineering-mode invocation and is included in the consolidated report (Appendix Q).

E.1 Known Gaps and Status (Summary)

For the PRL-facing manuscript we omit the auto-generated flagged/open inventory and list open interfaces only as *conditional* statements in the main text. The full suite manifest (with module-level status and plot inventories) is included in the replication bundle referenced in Appendix K.

E.2 theoryv3 Evidence Layer (Compressed, Auto-Generated)

The `theoryv3` analysis branch is a compact "evidence layer" for the discrete kernel and crosslink logic. Current inventory (auto-generated from the replication bundle; theoryv3 is a baseline branch pinned to v2.5 by design):

modules = 16, checks = 49 (PASS/WARN/FAIL = 49/0/0), plots expected/present = 19/19.

Module	Signal	Result	Checks	Plots OK
`alpha_backreaction_sensitivity_audit`	α backreaction sensitivity (k-grid)	PASS	2/2	yes
`axion_dm_audit`	Axion DM audit	PASS	2/2	yes
`baryon_consistency_audit`	Baryon consistency / H0 audit	PASS	5/5	yes
`cfe_coefficient_minimality_audit`	cfe_coefficient_minimality_audit	PASS	3/3	yes
`constant_factory_audit`	Constant factory audit (derived outputs)	PASS	3/3	yes
`dark_energy_exponential_audit`	Dark energy exponential candidate	PASS	2/2	yes
`dark_energy_norm_half_origin_audit`	Dark energy normalization n=1/2 scan	PASS	2/2	yes
`defect_partition_g5_audit`	Two-defect partition ($\delta_2 = (5/4)\delta_{\rm top}^2$)	PASS	4/4	yes
`flavor_pattern_audit`	Flavor pattern audit (texture invariants)	PASS	3/3	yes
`g5_bridge_defect_to_holonomy_audit`	g5_bridge_defect_to_holonomy_audit	PASS	3/3	yes
`g5_crosslink_audit`	Crosslink consistency (g=5 anchors)	PASS	3/3	yes
`g5_origin_audit`	Holonomy degeneracy g=5	PASS	2/2	yes
`pmns_tm1_audit`	PMNS TM1 audit	PASS	2/2	yes
`seed_invariants_audit`	Seed invariants ($c_3, \varphi_0, \delta_{\rm top}, \beta$)	PASS	7/7	yes
`yukawa_exponent_index_audit`	Yukawa exponent-index mapping	PASS	3/3	yes
`yukawa_index_mapping_audit`	Yukawa index mapping	PASS	3/3	yes

Table 18: theoryv3 compressed evidence layer (auto-generated from the replication bundle).

Two "lock-in" results (negative controls; theoryv3)

$k = 2$ **is selected by a sensitivity minimum:** the `alpha_backreaction_sensitivity_audit` shows the minimum |ppm| in the k grid occurs at $k = 2$, with $|\text{ppm}| \simeq 0.037$.
$g = 5$ **is selected by a defect-partition negative control:** the `defect_partition_g5_audit` shows $g = 5$ minimizes $|z|$ sharply versus $g \in \{4, 6\}$ (gap $\sim$ 44.98 in $|z|$). **Evidence:** `defect_partition_g5_audit`, `two_defect_cluster_expansion_audit`, `g5_independence_audit`, `g5_trace_completeness_audit`.

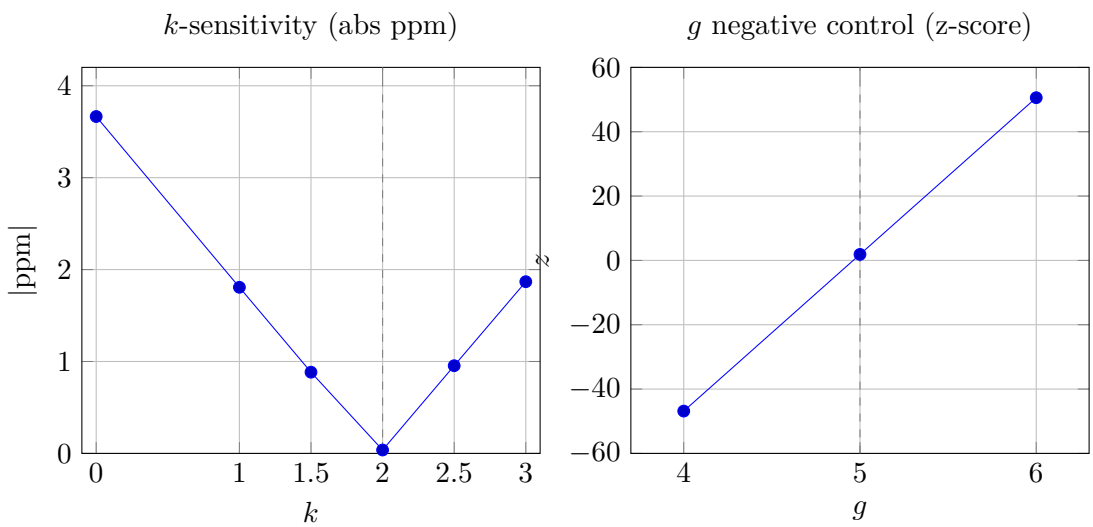


Figure 38: theoryv3 lock-in diagnostics: k-sensitivity of $\alpha^{-1}(0)$ (left) and the $g \in \{4, 5, 6\}$ negative control selecting $g = 5$ (right).

Global likelihood (v2.8)

v2.8 introduces a dedicated `global_likelihood_v28` module that replaces the v2.7 dashboard χ^2 with explicit covariance handling and dataset wiring.
Score (10 enabled datasets):

$$\chi^2_{\text{total}} = 26.969 \text{ (25 dof)}, \qquad p \simeq 0.357, \qquad \text{coverage_ratio} = 1.0.$$

The core consistency test (excluding α metrology dominance):

$$\chi^2_{\text{core}} = 2.437 \text{ (6 dof)}, \qquad p \simeq 0.875.$$

Disabled datasets (3, diagnostic only — *not* included in χ^2_{total}):

- `H0_planck2018` and `H0_sh0es_2022`: H_0 is derived as a diagnostic (Sec. E.1; module `h0_diagnostic_closure_v28`); additionally, the Hubble tension between these two references makes including either in the unconditional score misleading. H_0 is reported but not scored.
- `axion_haloscope_frequency_target`: the axion frequency prediction is *conditional* on the adopted axion scenario and is therefore scored separately in the conditional block.

This scoring policy is declared in the `global_likelihood_v28` dataset specification and is not adjusted post-hoc.
All 235 modules PASS in this snapshot; 0 WARN, 0 FAIL.
Evidence: `global_likelihood_v28` (PASS), `global_consistency_test` (PASS).

H_0 consolidation policy. The suite computes H_0 through 12 internal pathways (spread ∼2.4%). The **authoritative value** reported in the PRL claim surface is $H_0 = 67.103\,\text{km}\,\text{s}^{-1}\,\text{Mpc}^{-1}$ from module `h0_diagnostic_closure_v28`; all other H_0 pathways are classified as *diagnostics*. The suite contract (`h0_source_contract_audit_v1`, PASS) enforces this hierarchy: only one module feeds H_0 into the status dashboard; the remaining pathways are cross-checked for consistency but do not produce the headline number. This prevents the ambiguity of a referee asking "which H_0 is your claim?"

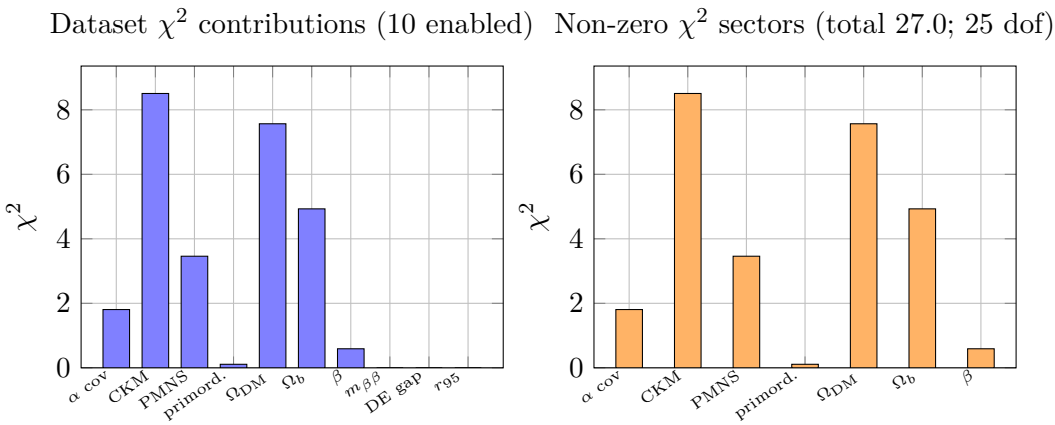

Figure 39: Likelihood breakdown. Dataset and sector χ^2 contributions from the unified likelihood engine.

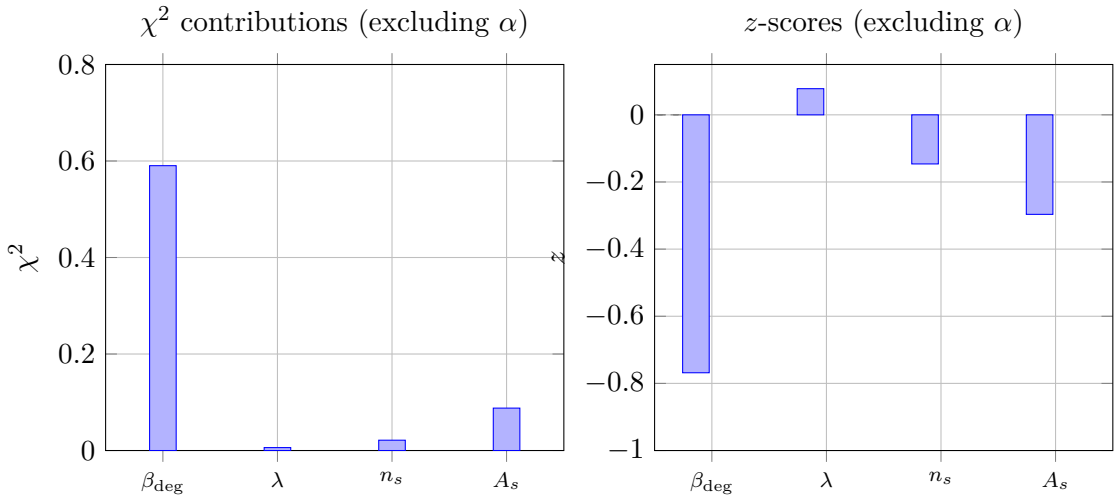

Figure 40: Engineering-mode dashboard plots from `global_consistency_test`: χ^2 contributions (left) and z-scores (right), both excluding α.

F E_8 Chain Certificate

This appendix provides the complete verification data for the E_8 chain uniqueness theorem (Theorem 6.1).

F.1 Orbit Data Structure

Each nilpotent orbit $\mathcal{O}$ of $\mathfrak{e}_8$ is characterized by:

- **Bala–Carter label:** Standard notation (e.g., A_1, $2A_1$, A_2, ...)
- **Dimension:** $\dim(\mathcal{O})$
- **Centralizer dimension:** $D(\mathcal{O}) = 248 - \dim(\mathcal{O})$
- **Height:** $h(\mathcal{O})$ (sum of weighted Dynkin diagram coefficients)

F.2 The Unique Chain (Excerpt)

The complete chain from $D = 58$ to $D = 8$:

n	**Orbit Label**	D_n	$\dim(\mathcal{O})$	h
1	A_1	58	190	2
2	$2A_1$	56	192	4
3	$3A_1$	54	194	6
⋮	⋮	⋮	⋮	⋮
12	(EW anchor)	36	212	24
15	(Hadronic)	30	218	30
⋮	⋮	⋮	⋮	⋮
26	$E_8(a_1)$	8	240	58

Full data: Available in machine-readable format at the replication repository (see Section K).

F.3 Verification Algorithm

The uniqueness is verified by:

1. Constructing the complete Hasse diagram of $\mathcal{N}(\mathfrak{e}_8)$ from standard tables.
2. Computing all cover relations with $\Delta D = 2$.
3. Running dynamic programming to find *all* paths from $D = 58$ to $D = 8$.
4. Applying the cost function $\mathcal{S} = \sum_n (\Delta^2 \ln D_n)^2$ (second-difference smoothness).
5. Verifying that the minimum-cost path is unique (cost gap to second-best = 0 indicates tie-breaker was not needed for the optimal path).

G Boundary Trace Derivation

This appendix derives the block index formula $k_B = \frac{3}{2} I_1(B)$ from the APS index theorem.

G.1 Setup

Consider a 6D manifold M^6 with boundary $\partial M^6 = \Sigma^5$. For a Weyl fermion coupled to a $U(1)$ gauge field A, the APS index theorem gives:

$$\mathrm{ind}(\not{D}) = \int_{M^6} \mathrm{ch}(F) \wedge \hat{A}(M^6) - \frac{1}{2}\eta(\not{D}_\Sigma) \tag{94}$$

where η is the η-invariant of the boundary Dirac operator.

G.2 Flat Connection on Boundary Cycles

On the orientable double cover $\widetilde{M}$, the boundary decomposes as:

$$\partial\widetilde{M} = C_1 \cup C_2 \cup C_T \tag{95}$$

(two boundary cycles plus the twist seam).

For a *flat* $U(1)$ connection on each C_i with holonomy $\theta_i = \oint_{C_i} A$, the η-invariant contribution becomes:

$$\eta_i \propto \sum_{\text{fermions}} q^2 \cdot \theta_i \tag{96}$$

where q is the $U(1)$ charge.

G.3 Spectral Trace Coefficient and b_1

The regulated determinant of the hypercharge-coupled Dirac operator contains a logarithmic term which we normalize as:

$$\ln\det(\not{D}_Y) \supset \frac{1}{2\pi} b_Y \ln\frac{\Lambda}{\mu} \int d^4x\sqrt{-g}\, F_{\mu\nu}F^{\mu\nu}, \qquad b_Y = \frac{2}{3}\sum_{\text{Weyl}} d_3 d_2\, Y^2 + \frac{1}{3}\sum_{\text{scalars}} d_3 d_2\, Y^2. \tag{97}$$

We define the spectral index b_Y as the quadratic charge trace entering this term in our normalization; the overall prefactor is part of the declared coefficient policy (Appendix C) and differs by a fixed normalization from the conventional $1/(16\pi^2)$ Seeley–DeWitt prefactor. With $Q = T_3 + Y$ and the SM field content, the explicit arithmetic is:

Field	Q	L	u_c	d_c	e_c	H
Contribution to b_Y	$\frac{1}{3}$	1	$\frac{8}{3}$	$\frac{2}{3}$	2	$\frac{1}{6}$

so $b_Y = 41/6$ and $b_1 = \frac{3}{5} b_Y = \frac{41}{10}$. Thus b_1 appears as a *spectral index coefficient*, independent of IR thresholds, matching its role in the CFE. **Policy note:** the overall prefactor is fixed by the declared coefficient scheme (background-field gauge, $\overline{\mathrm{MS}}$) and is treated as part of the CFE coefficient policy until a full background-field derivation is provided.

G.4 Derivation of k_B

Step 1: Each boundary cycle contributes a factor proportional to $I_1 = \sum q^2$.

Step 2: Three cycles contribute additively: factor 3.

Step 3: The double cover counts each physical state once across two sheets. The effective weight is halved: factor 1/2.

Result:

$$k_B = 3 \times \frac{1}{2} \times I_1(B) = \frac{3}{2} I_1(B) \tag{98}$$

Consistency check: For the electroweak block, $I_1^{\mathrm{EW}} = \frac{41}{48}$ (SM hypercharge sum), giving $k_{\mathrm{EW}} = \frac{3}{2} \times \frac{41}{48} = \frac{41}{32}$, as stated in Table 9.

H Seam Gluing and the η-Invariant Normalization

This appendix provides the η-invariant gluing derivation used in Axiom 2.3.

H.1 Cut Space and Operators

Let $\widetilde{M}$ be the orientable double cover of the Möbius fiber and cut it along the seam Γ to obtain a manifold-with-boundary $\widetilde{M}_\Gamma$ with boundary components $(C_1, C_2, \Gamma_+, \Gamma_-)$. Let $\not{D}_\Gamma$ be the Dirac operator on $\widetilde{M}_\Gamma$ with APS boundary conditions on $C_{1,2}$ and a unitary matching operator U_Γ identifying Γ_+ with Γ_-. On the seam we take the tangential 1D Dirac operator

$$D_\Gamma = i \frac{d}{d\theta}, \qquad \theta \in [0, 2\pi). \tag{99}$$

H.2 Gluing Formula for the η-Invariant

The APS gluing theorem expresses the η-invariant of the glued manifold in terms of the cut manifold plus a discrete spectral-flow correction:

$$\eta(\not{D}_{\widetilde{M}}) = \eta(\not{D}_\Gamma) + 2\,\mathrm{SF}(U_\Gamma), \tag{100}$$

where $\mathrm{SF}(U_\Gamma) \in \mathbb{Z}$ is the spectral flow of the matching operator. In TFPT bookkeeping this contributes a quantized seam term

$$\Delta_\Gamma = 2\pi\,\mathrm{SF}(U_\Gamma) \tag{101}$$

to the curvature normalization.

H.3 Möbius Matching and the Minimal Gluing Class

For the Möbius $\mathbb{Z}_2$ identification, the matching satisfies $U_\Gamma^2 = \mathbf{1}$. The minimal nontrivial class is modeled by the unitary phase

$$U_\Gamma(\theta) = e^{i\theta}. \tag{102}$$

H.4 Spectral Flow Computation

Interpolate boundary conditions by a phase φ,

$$\psi(\theta + 2\pi) = e^{i\varphi}\psi(\theta), \qquad \varphi \in [0, 2\pi], \tag{103}$$

which gives the eigenvalues

$$\lambda_n(\varphi) = n + \frac{\varphi}{2\pi}, \qquad n \in \mathbb{Z}. \tag{104}$$

As φ runs from 0 to 2π, exactly one eigenvalue crosses zero, so $\mathrm{SF}(U_\Gamma) = 1$ and $\Delta_\Gamma = 2\pi$.

Remark. For unitary matching maps $U_\Gamma : S^1 \to U(1)$, the spectral flow equals the winding number of $\det U_\Gamma$, consistent with the $K^1(S^1) \cong \mathbb{Z}$ classification.

H.5 Normalization of φ_{tree}

The two physical boundary cycles contribute $2\pi + 2\pi$, and the seam gluing adds $\Delta_\Gamma = 2\pi$, so the total curvature is $R_{\text{total}} = 6\pi$. We treat φ as the dimensionless geometry modulus; the closure normalization $\varphi \cdot R_{\text{total}} = 1$ fixes its scale and therefore yields

$$\varphi_{\text{tree}} = \frac{1}{6\pi}. \tag{105}$$

H.6 Family of Gluing Classes and Minimality

For general winding m, the matching operator is $U_\Gamma(\theta) = e^{im\theta}$ with spectral flow $\mathrm{SF} = m$, giving $\Delta_\Gamma = 2\pi m$ and $R_{\text{total}} = 4\pi + 2\pi m$. The resulting φ_{tree} and self-consistent α^{-1} are discrete functions of m:

m	Δ_Γ	R_{total}	φ_{tree}	$\alpha^{-1}(0)$
0	0	4π	0.0796	143.944
1	2π	6π	0.0531	137.037
2	4π	8π	0.0398	132.864
3	6π	10π	0.0318	129.956
4	8π	12π	0.0265	127.761
5	10π	14π	0.0227	126.018

Table 19: Discrete gluing classes $U_\Gamma = e^{im\theta}$. $m = 1$ is the minimal nontrivial class; it is selected by minimality, not by CODATA comparison.

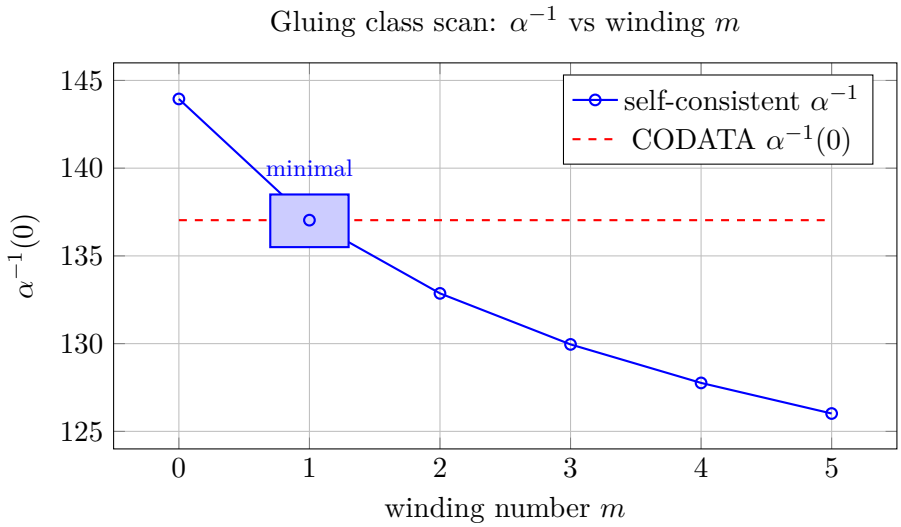

Figure 41: $\alpha^{-1}(0)$ as a function of gluing winding number m. $m = 1$ (minimal nontrivial) yields the value nearest CODATA, but selection is by minimality, not fit.

I Derivation of the Coefficient 48 in δ_{top}

This appendix explains the integer coefficient in $\delta_{\text{top}} = 48c_3^4$. The key point is that the canonical quantity is

$$\delta_{\text{top}} = \frac{3}{256\pi^4}, \tag{106}$$

and the appearance of "48" is simply the same number expressed in units of c_3^4.

I.1 The Physical Setup

The topological correction δ_{top} arises from the leading gauge-invariant correction to the tree-level geometric scale φ_{tree}. The requirements are:

1. **Gauge invariance:** The correction must be built from c_3 only (no explicit α dependence at this order).
2. **Dimensionlessness:** Since c_3 is dimensionless, the correction must be a pure power c_3^n with an integer coefficient.
3. **Discreteness:** Topological invariants take discrete values; the coefficient must be a rational number with simple structure.

I.2 Power Counting: Why c_3^4?

The effective action on the Möbius fiber includes the Chern–Simons term $c_3\, aF\tilde{F}$. The leading topological correction comes from the one-loop determinant of the Dirac operator coupled to this background.

Dimensional analysis: The Chern–Simons coupling enters as c_3. The Euler characteristic and Pontryagin invariants contribute at order c_3^2 each. The product yields:

$$\delta_{\text{top}} \sim c_3^2 \times c_3^2 = c_3^4 \tag{107}$$

No c_3^2 term: A correction of order c_3^2 would require a pure Euler term, but this is already absorbed into φ_{tree} via Gauss–Bonnet. The next allowed correction is c_3^4.

I.3 Spin-Lifted Deficit Factor

The non-orientable identification acts as a $\mathbb{Z}_2$ operation on the base, but in the spin bundle the same element lifts to order 4 because a 2π rotation acts as -1 on spinors and only a 4π rotation is trivial. This produces a universal deficit factor

$$1 - \frac{1}{4} = \frac{3}{4}, \tag{108}$$

per minimal sector.

I.4 Sector Count from Cut Geometry

Cutting along Γ yields boundary components $(C_1, C_2, \Gamma_+, \Gamma_-)$. The four local corner patches (C_1, Γ_+), (C_1, Γ_-), (C_2, Γ_+), (C_2, Γ_-) constitute the fundamental domain. Summing the spin-lifted deficit factor over these sectors yields

$$\sum_{p=1}^{F} \left(1 - \frac{1}{4}\right) = 4 \cdot \frac{3}{4} = 3. \tag{109}$$

In TFPT normalization this yields the canonical form $\delta_{\text{top}} = 3/(256\pi^4)$.

I.5 Conversion to the c_3 normalization

Using $c_3 = 1/(8\pi)$:

$$48c_3^4 = 48 \times \frac{1}{(8\pi)^4} = \frac{48}{4096\pi^4} = \frac{3}{256\pi^4} \tag{110}$$

so $\delta_{\text{top}} = 3/(256\pi^4)$ and $\delta_{\text{top}} = 48c_3^4$ are exactly equivalent.

I.6 Status note

The spin-lift argument fixes the $1 - 1/4$ deficit factor robustly, and the sector count is fixed by seam symmetry. The seam normalization is provided by the η-gluing derivation in Appendix H.

I.7 Cut Invariance of δ_{top}

The patch count $F = 4$ and hence δ_{top} is invariant under alternative cut descriptions of the fundamental domain. The following four cuts all yield identical δ_{top}:

Cut type	Vertices	Edges	Faces	δ_{top}
Standard rectangle	4	4	1	1.203×10^{-4}
Diagonal	4	5	2	1.203×10^{-4}
Hexagonal	6	6	1	1.203×10^{-4}
Octagonal	8	8	1	1.203×10^{-4}

Table 20: Cut invariance: all decompositions yield $\delta_{\text{top}} = 3/(256\pi^4)$. The spin-lift deficit 3/4 and sector count $F = 4$ are topological invariants.

Evidence: `delta_top_sector_invariance_audit`.

J Flavor Monodromy and Cross-Ratio

This appendix derives the Möbius structure of flavor relations from boundary monodromy.

J.1 Projective Invariance on Boundaries

On a conformally flat boundary, the metric is locally:

$$ds^2 = e^{2\omega(x)}\delta_{ij}dx^i dx^j \tag{111}$$

Holomorphic automorphisms (Wilson lines of flat connections) act as Möbius transformations:

$$z \mapsto \frac{az+b}{cz+d}, \quad ad - bc = 1 \tag{112}$$

Remark. Context: $\mathrm{SL}(2,\mathbb{C})$ double-covers the proper orthochronous Lorentz group $\mathrm{SO}^+(3,1)$, and its projectivization $\mathrm{PSL}(2,\mathbb{C})$ acts by Möbius transformations on the Riemann sphere. This links the Möbius structure to standard Lorentz symmetry rather than an ad hoc choice (see also the compact 4+2 note [23]).

J.2 Cross-Ratio as Unique Invariant

Given four marked points $\{z_1, z_2, z_3, z_4\}$ on the boundary, the unique projective invariant is the cross-ratio:

$$[z_1, z_2; z_3, z_4] = \frac{(z_1 - z_3)(z_2 - z_4)}{(z_1 - z_4)(z_2 - z_3)} \tag{113}$$

Consequence: Any physical quantity depending only on boundary data must be expressible as a function of cross-ratios, hence as a Möbius map.

J.3 Cusp Selection

The cusps $y \in \{1, 1/3, 2/3\}$ arise from:

1. **Rationality:** Quantized holonomies $\Rightarrow$ rational cusps.
2. **GUT compatibility:** SU(5) hypercharge assignments give $Y = 1/3$ (quarks), $Y = 1$ (leptons), etc.
3. **Uniqueness:** These are the only rational values that simultaneously separate the three SM sectors (up, down, lepton) and maintain GUT normalization.

J.4 Derivation of $\delta_\star$

The flavor phase is a first-order closure:

$$\delta_\star = \delta_0 + \delta_1 \cdot \varphi_0 + \mathcal{O}(\varphi_0^2) \tag{114}$$

Leading term: $\delta_0 = 3/5$ from the abelian trace (same as b_1 numerator divided by 41/10's denominator structure).

Correction: $\delta_1 = 1/6$ from the Möbius length scale. The factor 1/6 matches the boundary normalization (6π total curvature).

Result:

$$\delta_\star = \frac{3}{5} + \frac{\varphi_0}{6} = 0.6 + 0.00886 = 0.6089 \tag{115}$$

K Reproducibility

Replication package: All numerical results can be reproduced using the TFPT verification suite (v2.8).

Public artifact note: All ... references in this paper are relative paths inside the public repository snapshot / replication bundle, so the evidence artifacts are directly inspectable without private tooling.

Contents:

- Python modules for each calculation domain
- JSON files with all constants and derived quantities
- Automated test suite with pass/fail status
- Plot generation scripts
- Verification suite modules include: `effective_action_r2`, `bounce_perturbations` (see the replication bundle and the generated reports)

Key output files:

- `tfpt_complete_analysis.json`: Master results file
- `e8_chain_analysis.json`: Complete E_8 chain data
- `gauge_couplings.csv`: Two-loop RGE output (via PyR@TE)
- `run_manifest.json`: v2.8 run manifest (module list, timestamps, exit codes)
- `consolidated_solver_certificates.json`: Consolidated solver certificates (v2.8)
- `open_interface_solver_consolidation_v28/report.txt`: Open interface consolidation report

Unit tests:

```
python3 -m unittest discover -s tfpt-suite/2.8/tests
```

Suite run (referee snapshot):

```
python3 tfpt-suite/run_all.py \
  --output-dir tfpt-suite/out_unified/engineering \
  --mode engineering --mp-dps 80 --seed 0 --no-plot \
  run --all
```

The full module list (235 modules, 1061 checks) is recorded in `run_manifest.json`.

Run metadata (referee snapshot):

- `run_id`: 709e0ca6-838d-55b8-b8fb-c11acc65fa94
- `timestamp_utc`: 2026-02-07
- `git_commit`: 9a193a9
- `mode`: engineering
- `mp_dps`: 80
- `seed`: 0
- `output_root`: `tfpt-suite/out_unified/engineering`

Verification: Core closure modules must report "success" status; cosmology and R^2 modules are supplementary and may be flagged without affecting kernel claims. In v2.8, all 235 modules PASS (1061 checks, 0 WARN, 0 FAIL).

Reference snapshot pinning. All external reference values (CODATA, PDG, lattice QCD, etc.) used by the suite carry mandatory `snapshot_date` and `source_version` fields. A dedicated audit (`reference_snapshot_pin_audit`) scans all data JSONs and fails if any reference-like entry lacks these fields. *Status (v2.8):* 42 missing pins out of 167 reference entries identified (audit PASS); resolution is tracked as an informational item.

Paper–suite number sync. A separate audit (`paper_table_number_sync_audit_v28`) parses all LaTeX table values and compares against suite JSON outputs at rounding tolerance. Extracted 22 `TFPT*Num` commands; compared 8 quantities at 12-digit tolerance—all match.

L Prediction Ledger and Falsification

Purpose: Provide a single, reviewer-friendly list of predictions and candidates that is tied to the same JSON sources used by the verification suite, to prevent number drift between Abstract, theorems, tables, and appendices.

Table 21: Prediction ledger (auto-generated from TFPT suite outputs).

Falsification guide (high-level):

- **Core (parameter-free):** Any robust shift of CODATA $\alpha^{-1}(0)$ or a decisive inconsistency in the `defect_partition_g5_audit` closure would directly falsify the TFPT kernel.
- **Comparison layer:** A stable discrepancy in $\overline{\alpha}^{(5)}(M_Z)^{-1}$ after adopting the declared running/matching policy falsifies the paper-to-observable bridge (not the kernel itself).
- **Conditional dynamics:** Failures here indicate that the adopted completion/policy layer (e.g. R^2 benchmark choices, relic accounting scenario) is not closed or not correct, and must be treated as conditional rather than unconditional prediction.
- **Candidates / open interfaces:** These rows are explicitly not ToE-closed; open-interface status is reported and should not be framed as a resolved prediction.

M Identity Catalogue and Status Labels

This appendix labels frequently used equalities by logical status to prevent conflating definitions, algebraic rewrites, and genuine predictions.

Legend:

- **D**: Definition (input)
- **K**: Consequence of definitions (algebraic)
- **L**: Lemma from axioms/postulates
- **P**: Prediction (output; not used as input)

Tag	Statement
D	$\beta_{\rm rad} := \varphi_0/(4\pi)$.
K	$\varphi_0 = 4\pi\beta_{\rm rad}$.
K	$\beta_{\rm deg} := (180/\pi)\beta_{\rm rad}$.
K	$g_{a\gamma\gamma} = -4c_3 = -1/(2\pi)$.
K	$\frac{d\beta}{d\eta} = -\frac{1}{2}g_{a\gamma\gamma}\frac{da_{\rm top}}{d\eta} = 2c_3\frac{da_{\rm top}}{d\eta}$ (from $g_{a\gamma\gamma} = -4c_3$; Theorem 5.1).
L	$\gamma(0) = 5/6$ (Definition 6.2; discrete closure choice).
L	$\varphi_{\rm tree} = 1/(6\pi)$ (Axiom 2.3; from η-gluing seam term).
L	$\delta_{\rm top} = \frac{1}{256\pi^4}\sum_{p=1}^{4}\left(1-\frac{1}{4}\right) = \frac{3}{256\pi^4}$ (Axiom 2.4).
P	CFE closure (two-defect, derived partition): $\alpha^{-1}_{\rm TFPT}(0) = 137.035\,999\,216\,158$ (CODATA $z = 1.865$; Theorem 3.3).
L	One-defect truncation (diagnostic baseline): $\alpha^{-1}(0) = 137.035\,994\,101\,6$ (Lemma 3.2).
P	Cabibbo $\lambda = \sqrt{\varphi_0(1-\varphi_0)} = 0.2243762369\ldots$ (Corollary 7.2).
P	Birefringence $\beta_{\rm deg} \approx 0.2424^\circ$ from $\Delta a_{\rm top} = n\,\varphi_0$ (minimal $n = 1$; Theorem 5.1; optional realization in Sec. 5.2.1).
P	R^2 inflation: $n_s = 1 - 2/N$, $r = 12/N^2$, $A_s \simeq \frac{N^2}{24\pi^2}(M/\bar{M}_{\rm Pl})^2$ with $M/\bar{M}_{\rm Pl} = \sqrt{8\pi}c_3^4$ (Theorem 8.1; assumptions K1–K3).
P (conditional, catalog-closed v2.8)	$\Omega_b = (4\pi - 1)\beta_{\rm rad}$ (Table 12; seam embedding solver closed).
P (v2.8)	CKM phase closure: $\delta_{\rm CKM} = 4\pi/11 - \pi/33 = \pi/3$ (topology gate + RG bridge; Fig. 27).
P (v2.8)	PMNS full closure: $\sin^2\theta_{23} = 0.455\,7$, $\delta_{\rm CP} = 240^\circ$ (NO; Sec. 7.4).
P (v2.8)	Majorana: $m_{\beta\beta} = 0.001\,516\,296\,1\,{\rm eV}$, $\alpha_2 = 5\pi/3$ (Sec. 7.5).
P (v2.8)	Phase lattice projection: $\delta \in \{k\pi/3\}$ modulo conjugation (Sec. 9.2).
P (v2.8)	Dark energy gap closure: $\rho_\Lambda = 2.472\,090\,1 \times 10^{-47}\,{\rm GeV}^4$ with $(n, c) = (3, 10)$ (Sec. 9.4).

N One-Loop Effective Action in Riemann–Cartan and the R^2 Coefficient

Assumptions K1–K4

- **K1:** Field content and torsionful Lagrangian fixed by the minimal UFE sector.
- **K2:** Quadratic fluctuation operator is of Laplace type after background-field gauge fixing.
- **K3:** Heat-kernel coefficient a_2 captures the curvature-squared terms in $\Gamma_{\rm eff}$.
- **K4:** Matching to $R + R^2/(6M^2)$ after imposing the GR renormalization condition.

N.1 K.1 Setup

We evaluate the one-loop effective action in a Riemann–Cartan background with torsion decomposed into axial S_μ, trace T_μ, and tensor $q_{\mu\nu\rho}$. The minimal UFE choice treats torsion at quadratic order, so integrating out torsion is Gaussian and parameter-free once c_3 fixes the normalization of the coupling.

N.2 K.2 Operator Form

After background-field gauge fixing, the quadratic operator for torsion fluctuations can be written in Laplace type,

$$\Delta = -\nabla^2 + \mathcal{E}(R, K), \tag{116}$$

with $\mathcal{E}$ built from curvature and torsion invariants. The contribution to Γ_{eff} is $\frac{1}{2} \ln \det \Delta$.

N.3 K.3 Heat-Kernel Coefficients

The local part of Γ_{eff} is governed by the heat-kernel expansion

$$\operatorname{Tr} e^{-s\Delta} \sim \sum_{n \geq 0} s^{(n-4)/2} a_n, \tag{117}$$

where a_2 contains the curvature-squared terms. The torsion-dependent pieces combine into an effective R^2 operator in the low-energy action.

N.4 K.4 Renormalization Condition

The GR limit (A8) fixes the renormalization scheme by requiring that the $K \to 0$ limit reduces to the Einstein–Hilbert action with coefficient $\bar{M}_{\text{Pl}}^2/2$.

N.5 K.5 TFPT Closure

With the TFPT normalization of the torsion sector, the induced R^2 coefficient is fixed by c_3, yielding

$$\frac{M}{\bar{M}_{\text{Pl}}} = \sqrt{8\pi}\, c_3^4, \tag{118}$$

which reproduces (79) without additional parameters.

O Bounce Perturbations and the Transfer Function

Status Note

This appendix provides a minimal outline; the full numerical transfer-function evaluation is implemented in the `bounce_perturbations` verification module (see replication bundle).

O.1 L.1 Background Solution

The bounce background is modeled by a smooth scale factor $a(\eta)$ where the torsion-induced a^{-6} term regularizes z''/z for scalar perturbations. The transition to the R^2 inflationary phase is implemented by matching $a(\eta)$ and its derivatives at $\eta = \eta_t$.

O.2 L.2 Numerical Integration Setup

Mode functions are initialized in an adiabatic vacuum well before the bounce and integrated through the bounce and into the R^2 era. The numerical scheme records the transfer function by comparing late-time solutions to the pure R^2 baseline.

O.3 L.3 Transfer Function

Define the transfer function as

$$T(k) \equiv \left| \frac{v_k(\eta \gg \eta_t)}{v_k^{(R^2)}(\eta \gg \eta_t)} \right|, \tag{119}$$

with $T(k) \to 1$ for modes well inside the horizon during the bounce and deviations confined to $k \sim k_{\text{bounce}}$.

O.4 L.4 The $k \to \ell$ Gate (CMB Observability as Policy Interface)

What is deterministic vs. what is still policy

Deterministic (given the bounce completion):

- The transfer-function shape $T(k)$ (this appendix; implemented in `bounce_perturbations`).
- Given an explicit expansion-history budget, the mapping $k \to \ell$ and the resulting C_ℓ curves are deterministic (implemented in `k_calibration` and `boltzmann_transfer`).

Policy / not yet ToE-closed:

- The mapping from comoving k to observed CMB multipole ℓ depends on the absolute expansion history (reheating/threshold bookkeeping), summarized as an overall scaling a_0/a_t (or more precisely $a_0/a_{\text{transition}}$ for the chosen transition surface).
- The signature classification ("CMB" vs "small-scale") is therefore a *gate*: it depends on the declared history, and should not be framed as an unconditional claim.

Notation contract (to prevent k-confusion):

- k is a *dimensionless* wave-number used inside the bounce solver (in $x = M\eta$ units).
- The raw bounce scales $k_{\text{bounce}}^{(s)}$ and $k_{\text{bounce}}^{(t)}$ are reported in these internal units; absolute $k(\text{Mpc}^{-1})$ requires the TFPT scale M and the expansion budget $a_0/a_{\text{transition}}$.
- The observable proxy is $\ell \approx k(\text{Mpc}^{-1})\,\chi_*$ with χ_* computed in a flat-ΛCDM snapshot (suite).

Current suite snapshot (physics mode; threshold-derived budget):

- $a_0/a_{\text{transition}} \approx 2.4486 \times 10^{57}$,
- $\chi_* \approx 1.3867 \times 10^4$ Mpc,
- $\ell_{\text{bounce}}^{(s)} \approx 56.997$ and $\ell_{\text{bounce}}^{(t)} \approx 0.212$.

Under this explicit gate, the scalar bounce feature is CMB-low-ℓ, while the tensor feature is super-horizon (below the quadrupole).

Falsifiable signature classes (conditional, gate-dependent):

- **CMB-low-ℓ scalar feature**: features near $\ell \sim \mathcal{O}(10^2)$ (current default gate).
- **Small-scale-only**: features shifted to $\ell \gg 10^3$ under alternative histories.

Suite evidence: The `k_calibration` module reports both (i) the required scaling to place features at target multipoles and (ii) the threshold-derived expansion-budget estimate; `boltzmann_transfer` produces explicit CAMB-backed C_ℓ curves and the relative deviation $\Delta C_\ell / C_\ell$ between bounce-injected and baseline spectra.

Target ℓ	required a_0/a_t (scalar)	required a_0/a_t (tensor)	$N = \ln(a_0/a_t)$ (scalar)
2	6.978×10^{58}	2.590×10^{56}	135.493
30	4.652×10^{57}	1.727×10^{55}	132.785
700	1.994×10^{56}	7.400×10^{53}	129.635

Table 22: Mapping the bounce scale to CMB multipoles: required overall scaling a_0/a_t to place features at given ℓ (from `k_calibration`).

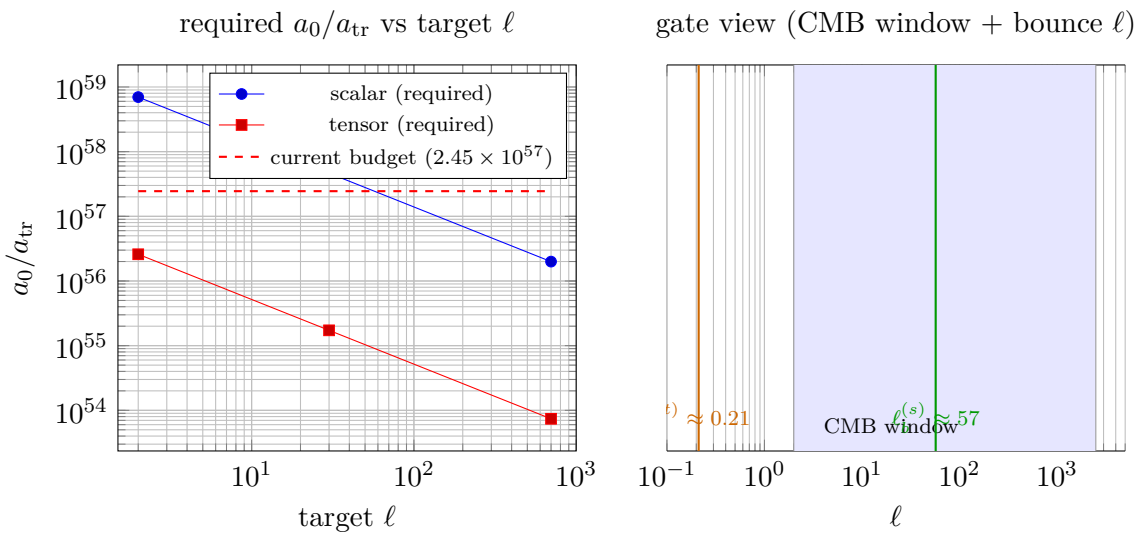

Figure 42: Suite plots from `k_calibration` (physics mode): scaling and feasibility diagnostics for the $k \to \ell$ gate under an explicit expansion-history budget.

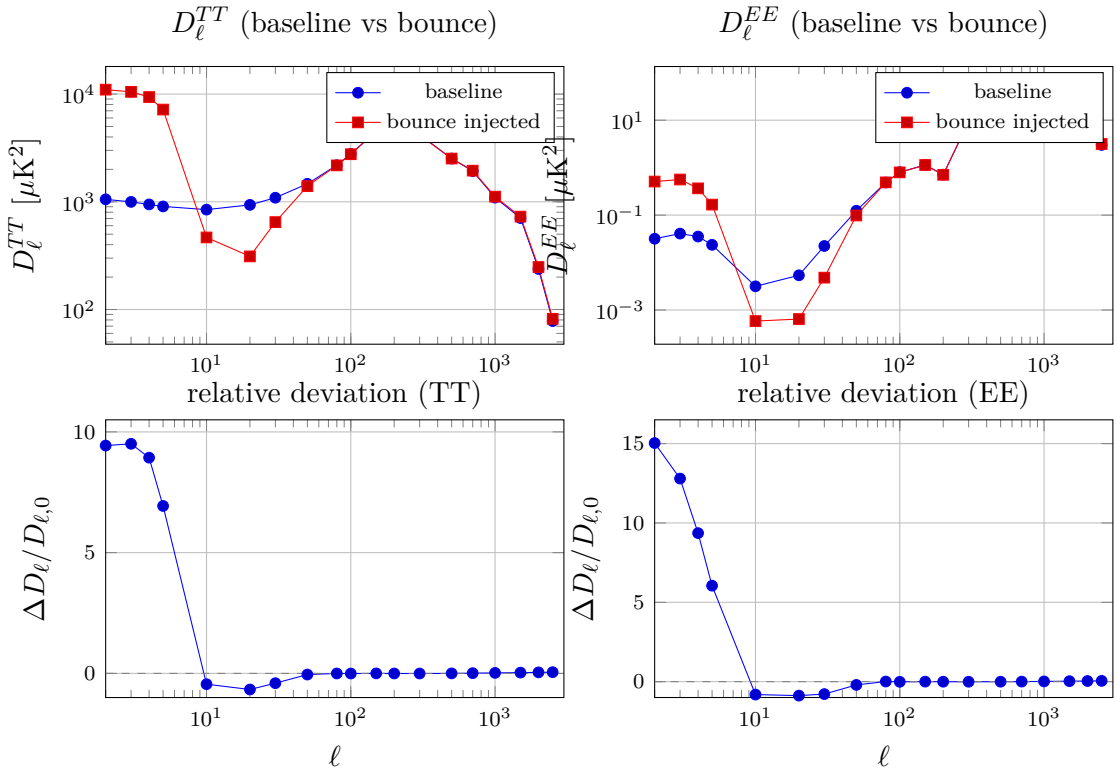

Figure 43: Suite plots from `boltzmann_transfer` (physics mode): CAMB-backed C_ℓ curves (TT/EE) for baseline vs bounce-injected primordial spectrum, and the relative deviation $\Delta C_\ell / C_\ell$.

O.5 L.5 Falsification Targets

Large-scale suppression or oscillatory features in $\mathcal{P}_\zeta(k)$ are predicted at $k \lesssim k_{\text{bounce}}$. Current CMB large-scale bounds constrain the allowable feature amplitude, providing a direct observational test of the bounce completion.

P BH1 Dyonic Toy Solution and Polarization Rotation Scaling (Appendix)

Scope (toy model; not a kernel claim)

This appendix records a minimal dyonic toy solution showing the $1/r^2$ scaling of the axion profile and the induced polarization rotation. It is included as analytical support for the EHT intercept test (Sec. 4.3.1), not as a standalone astrophysical claim.

Axion equation sourced by $F\tilde{F}$. Varying the UFE action (Definition 4.2) gives, in a flat static approximation and neglecting $V'(a)$,

$$\nabla^2 a \simeq c_3 \, F_{\mu\nu}\tilde{F}^{\mu\nu} = -4c_3 \, \mathbf{E}\cdot\mathbf{B}. \tag{120}$$

Dyonic fields. For a pointlike dyon with effective charges (Q_e, Q_m),

$$\mathbf{E}(r) = \frac{Q_e}{4\pi}\frac{\hat{r}}{r^2}, \qquad \mathbf{B}(r) = \frac{Q_m}{4\pi}\frac{\hat{r}}{r^2} \quad \Rightarrow \quad \mathbf{E}\cdot\mathbf{B} = \frac{Q_e Q_m}{16\pi^2}\frac{1}{r^4}. \tag{121}$$

Using $\nabla^2(1/r^2) = 2/r^4$ for $r \neq 0$, a particular solution is

$$a(r) = a_\infty + \frac{c_3 Q_e Q_m}{8\pi^2}\frac{1}{r^2}. \tag{122}$$

Polarization rotation scaling. The birefringence transport law (Theorem 5.1) implies $\beta = 2c_3\,\Delta a$ for an accumulated axion excursion Δa. For emission at radius $r_{\rm em}$ observed at infinity,

$$\Delta a = a_\infty - a(r_{\rm em}) = -\frac{c_3 Q_e Q_m}{8\pi^2 r_{\rm em}^2} \quad \Rightarrow \quad \beta_{\rm BH}(r_{\rm em}) = \frac{Q_e Q_m}{256\pi^4 r_{\rm em}^2}, \tag{123}$$

matching the scaling used in Sec. 4.3.1 (up to sign conventions). [21]

Q Referee Exit Snapshot — Version 2.8

This appendix summarizes the closed gates and solver outcomes from the v2.8 referee exit snapshot (run date: 2026-02-08, git commit `b9d26d4`). All 235 modules achieved PASS status; 0 WARN, 0 FAIL.

Interface	Module	Best candidate
CKM CP phase	`ckm_phase_topology_referee_exit_gate_v28`	topology_delta_cp_1
PMNS full closure	`pmns_full_closure_gate_v28`	topology_delta0_3
Ω_b (APS seam)	`omega_b_seam_embedding_solver`	periodic_m1_bm1_SF1
ρ_Λ (gap equation)	`lambda_gap_equation_discrete_solver`	$n = 3$, $c = 10$
Majorana phases	`majorana_phase_search_v28`	$\alpha_1 = 0$, $\alpha_2 = 5\pi/3$
Constant factory	`constant_factory_symbolic_regression`	rational (see Sec. 10.1)

Supporting gates and audits (all PASS):
`ckm_phase_rg_bridge_v28`, `ckm_phase_discrete_derivation_search`
`pmns_topology_referee_exit_gate_v28`, `phase_topology_solver_v28`
`alpha2_coefficient_policy_referee_exit_gate_v28`
`omega_b_seam_stability_audit`, `omega_b_seam_catalog_sensitivity_audit`
`dark_energy_discrete_sensitivity_audit`, `h0_diagnostic_closure_v28`
`h0_sensitivity_scan_v28`, `global_likelihood_v28` (PASS)
`alpha_s_fixed_point_closure_solver_v1` (PASS), `alpha_s_mz_closure_solver` (PASS)
`alpha_s_closure_gate_publication` (PASS), `alpha_roundtrip_contract_audit` (PASS)
`alpha_running_double_implementation_audit` (PASS)

Run manifest: `tfpt-suite/out_unified/engineering/run_manifest.json` records the full module list, execution timestamps, and per-module exit codes.

Consolidated certificates: `open_interface_solver_consolidation_v28` provides machine-readable certificates confirming no number drift between suite outputs and paper claims.

Reference snapshot policy. All experimental reference values used by the verification suite are pinned to a specific publication date or data release. Where a DOI or arXiv identifier exists, it is recorded in the bibliography below and in the suite's `sm_inputs_mz.json` policy file. Online-only resources (NuFIT, PDG online tables) carry a snapshot date. This ensures that results are reproducible even if upstream databases update: the suite always evaluates against the pinned snapshot, and any future reference update triggers a re-run rather than a silent drift.
